THE INCREASING FREQUENCY OF INHERITED SYPHILIS AND THE GRAVE IMPORTANCE OF ITS EARLY RECOGNITION IN INFANTS AND YOUNG CHILDREN FROM THE STANDPOINT OF THE OPHTHALMOLOGIST.

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

FOR many years the ocular lesions of inherited syphilis in young children have deeply interested the writer, and for the last ten years his special attention has been directed toward the early recognition of these lesions or stigmata in infants and very young children.

I think we will all agree that the gravest, by far the most serious, consequences of syphilis are those due to heredity. One of the greatest of social dangers is the high rate of infant mortality among the children of syphilitic parents; but a greater one is the disastrous results of heredity in those who live to maturity. Many of them pass through a stunted childhood into a still more stunted manhood or womanhood, to become a permanent charge upon their family or upon the state. The position assumed and maintained by the state and municipal authorities toward the so-called "social diseases" is eminently false, and has largely to do with the widespread ignorance on the part of the public of the far-reaching disastrous effects of such diseases. It should be the duty of the medical profession to demand from the authorities the right of the public to protection from these diseases as from any contagious disease, and for three reasons: (1) That the innocent may not suffer. (2) That the State may not be compelled to support stunted children. (3) That racial degeneracy may be avoided.

In many of these cases of inherited ocular syphilis the lesions, or stigmata, are so ill-defined as not to be recognized except by the alert observer. Hence the examination should begin with the new-born infant, and should be repeated at brief intervals through early childhood to youth. One reason for this very early examination is to enable us to determine what proportion of these cases of ocular syphilis are actually fetal in origin. The case of prenatal, intrauterine ocular syphilis, especially of the deeper tissues of the eye, are far more frequent than is usually supposed, and the intrauterine infection runs its destructive course much more rapidly than where the ocular infection develops after birth.

It is a mistake to suppose that congenital syphilitic lesions of the eye run a mild course, for while some of these syphilitic infants are still-born or die in early infancy, many of the so-called *bad cases* live through infancy and childhood, but with very extensive ocular and aural stigmata. The ocular lesions may be confined to the lids and conjunctiva or cornea, or they may involve any or all of the deeper structures of the eye. My own experience has shown me that in very young infants lesions of the uveal tract are more frequent than keratitis as evidence of congenital syphilis. Iritis at birth is not a very uncommon lesion, and while it may exist alone, it is more commonly associated with chorioiditis. It is not always easy of recognition, owing to the external symptoms being but slightly marked or because of a coexisting keratitis with corneal opacity, but it should be carefully looked for. When the pupillary space is not blocked by exudation, an ophthalmoscopic examination should be made and a chorioiditis will often be revealed. I have seen this condition many times in infants at birth, and when found it is always associated with the stigmata of defective nutrition and the signs of facial senility. The symptoms are often so slight as to escape casual observation, and this is especially true of the ciliary injection and the free exudation into the field of the pupil. One reason why the lesions of the uveal tract have not been recognized at birth is that the period of their development has been placed later during the fifth or sixth month of life and hence their appearance at an earlier period has not been looked for. The lesion may be confined to one eye or involve both, and, like most cases of plastic iritis, it is liable to relapse.

The prognosis as to vision is largely influenced by the coexistence of other ocular stigmata and also by the degree of severity of the syphilitic saturation; and this I believe to vary in proportion with the length of the period which has elapsed since the parents contracted the disease and also with the fact of one or both parents being infected.

These lesions of the uveal tract in very young infants can, however, usually be recognized because at this early age interstitial keratitis is very rare. It is probable that the uveitis in infants seriously involves the retina, but as most of these unfortunate children die in infancy or early childhood, no proper tests of vision can be made. When the disease occurs later in child life, I am inclined to think that the retina suffers but slightly, for I have examined a number of cases of extensive chorioiditis which I have followed from the initial appearance of the lesion to an age when vision could be tested, and have been particularly impressed by the extremely good visual acuity existing after a very extensive chorioiditis. This disproportion between the actual condition of the chorioid and the existing visual acuity is a very striking feature. But I have never observed this in those cases of the prenatal or infantile chorioiditis who lived to reach the age of childhood when the vision could be tested.

This disproportion between the ophthalmoscopic findings and the actual visual acuity in the chorioiditis of childhood does not exist in the cases of retinitis and optic neuritis. The retinitis due to inherited syphilis in infants and young children seems always to lead to permanent changes in the retina, varying from faint white lines along the smaller arterial branches to entire obliteration of the vessels. In optic neuritis in these very young patients the end is, in may experience, always partial or complete atrophy. It is probable that of all inherited morbid tendencies, the inherited syphilitic taint is met with the most frequently in all classes of life, and the stigmata are extremely variable in number and degree, and often most elusive. In a family of syphilitics there is often a marked difference in the extent and number of the stigmata. There may be many stigmata in different parts of the body or there may be but a single well-marked stigma. Some of the stigmata may be so slight and elusive as to escape all but the keenest observation. There may be a history of some serious ocular inflammation pointing to interstitial keratitis or iritis, and yet examination shows a smooth unclouded cornea and an apparently normal iris. But if we search very carefully, we will find some very slight deformity in the pupillary margin or some irregularity in the shape of the cornea, usually a malformation of the oval type. The coincidence of interstitial keratitis and a vertically oval cornea is not infrequently observed, and I have noted it for years. Recently *Fuchs* has called attention to it in an admirable short paper read before the British Medical Association in July, 1909, and published in the *Ophthalmic Review* for September, 1909. It may exist in one eye only, but is usually found in both eyes. If attention is attracted by the corneal malformation in a patient, a more careful examination will reveal traces of very faint opacities, the remains of former interstitial keratitis which were not suspected. *Fuchs* is inclined to believe that an oval cornea is much more frequent in cases of inherited syphilis, and especially in those patients in whom interstitial keratitis has occurred or may be expected to occur, than in other patients.

This malformation of the cornea, however, like other stigmata of inherited syphilis, should not, when considered alone, be regarded as absolute proof of the disease.

We must look for the stigmata in all cases, even when there is no positive evidence of ocular disease. As this paper is restricted to a consideration of the lesions and stigmata in young children, we cannot expect much assistance from the dental stigmata, as the permanent teeth are not yet in evidence, but the ocular and aural stigmata are to be found when carefully looked for.

As regards the aural stigmata, the first question is as to the occurrence of any pain, inflammation or discharge from the ears, acute or chronic, in infancy or very early childhood. Examination of the ears will then reveal scars or persisting perforations of the membrana tympani, or more or less complete destruction of the ossicula. If these are not found, then the hearing is to be tested for functional disturbance, though not much can be expected from these tests. But there is a variety of aural trouble without appreciable lesion, which is occasionally met with in young children, known as the *"surdité foudroyante,"* which is undoubtedly due to inherited syphilis. As is well known, this is characterized by great suddenness of its invasion, rapid course and intensity, ending in total loss of hearing in a few days or hours without any visible clinical evidence. Such an attack, coming on unheralded in a child with apparently normal hearing, is almost pathognomonic of inherited syphilis. This condition resists all treatment, and the patient remains permanently deaf. As a natural result of such attacks coming on in early childhood, there may be noticed certain defects of speech, varying in degree to actual mutism.

The ocular or aural stigmata are often accompanied by facial stigmata, especially on the forehead or nose, often so slight as not to be noticed. In infants and young children the actual congenital malformations are rare, and in themselves are not as significant as the acquired malformations. They consist in a flattening and broadening at the base of the nose, just beneath the frontal spine or in what is usually known as "snub nose," in which the bridge or line of the nose, instead of presenting a straight or slightly undulating line, assumes a concave or re-entering curve. Further confirmatory evidence of the syphilitic origin of the ocular stigmata may often be found in various congenital cranial stigmata, with which we are all familiar. There are certain conditions found in the teeth of the first dentition which are strongly suggestive of inherited syphilis. One of these is microdontism, in which some of the teeth are very small, while others are of normal size, and this condition is almost entirely in the upper and lower incisors. The difference in size is sometimes so slight as to escape all but the closest observation. Another condition which I have noted in many children with inherited syphilis, and on which *Fournier* lays great stress, is the persistence or permanence of the first teeth far beyond the usual period, thus vitiating the development of the permanent teeth. These two dental conditions in very young children often aid in establishing or confirming our diagnosis. In studying any series of cases we should try to estimate the real significance and value of the stigmata presented as aids to diagnosis of inherited syphilis. In the case of the existence of only one stigma, if the examination of other members of the family reveals the presence of other stigmata, then the one stigma points to the correct diagnosis of inherited syphilis. As before stated, it is not uncommon for syphilitic infants to be born with already well-marked evidence of disease of the uveal tract. This is an additional proof that the "fetus in utero" may suffer from inherited syphilis, and yet be born at full term and live.

As regards the internal lesions of the eye, I believe their apparent rarity is due to the fact that the external evidences are often but slightly marked, and therefore they have not been looked for.

It is a paramount necessity to recognize the stigmata at the very earliest age, if we are to do anything for the restoration of useful vision; and to recognize them we must look for them. I have recently had under my care a female infant, aged eleven months, with complete posterior synechias in both eyes and a thin membrane filling the pupillary space. The iris bulged toward the cornea, there was increased tension, all pointing to the future development of infantile glaucoma or buphthalmos. An iridectomy was done in each eye and the glaucomatous tendency was arrested at least temporarily. The ophthalmoscope showed a transparent lens and well-marked signs of a previous chorioiditis. In conclusion I would again call attention

briefly to the therapeutical deductions which Fournier has drawn from his immense clinical experience, and quoted by me two years ago. Fournier lays down four propositions, as follows:

1. Specific treatment is indicated in all cases in which the patients are actually affected by lesions or symptoms which might be due to syphilis and who show at least one of the stigmata mentioned.

2. If a patient shows one or more of the stigmata mentioned, he should be subjected to specific treatment as a prophylactic measure, if there be no actual lesion present.

3. In a recognized syphilitic family if a child has recently been born who presents one or more of the stigmata the parents should be submitted to prolonged specific treatment in order to prevent, if possible, the transmission of the taint to any future births.

4. In case a woman becomes pregnant in a family in which the children previously born show some of the stigmata above mentioned she is to be subjected to rigid specific treatment during her entire pregnancy.

To these four propositions laid down by Fournier. I am inclined to add a *fifth*, based upon my own experience during the last twenty-five years, viz.:

5. A patient who has contracted the disease and has presented undoubted evidences of constitutional syphilis, should be rendered sterile, in order to save the innocent and to prevent the degeneracy of the race.

47 West Thirty-sixth Street.

HINTS FOR THE GENERAL PRACTITIONER ON THE NATURE, ETIOLOGY, AND EARLY DIAGNOSIS OF INSANITY.*

By CARLOS F. MACDONALD, A.M., M.D.,

NEW YORK.

PROFESSOR EMERITUS OF MENTAL DISEASES AND MEDICAL JURISPRUDENCE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; EX-PRESIDENT NEW YORK STATE COMMISSION IN LUNACY.

In view of the fact that this body is composed largely of general practitioners, or at least of physicians whose practice is not devoted to psychiatry, it occurred to me that I could best utilize the time allotted to me to-day by offering a few suggestions along the lines indicated by the title of my paper.

"The care of the human mind is the most noble branch of medicine." Thus wrote Grotius more than two hundred years ago, and yet, despite the general acceptance of this declaration as a truism, there still remains in the public mind, as a relic of the Middle Ages when every insane person was believed to be possessed of a devil and was treated accordingly, a disposition, even among the more intelligent portions of the community, to regard the existence of insanity as a stigma somewhat akin to shame and disgrace, and, therefore, something to be denied or concealed. This notion doubtless arises from ignorance of the true nature of insanity, and is one which the medical profession should strive to dispel by the dissemination among the laity of correct ideas as to the real nature of this affection, namely, that it is a pathological condition; in other words, a physical disease or disorder, which, if properly placed under appropriate treatment, is susceptible of cure in a considerable proportion of cases, and that the chances of recovery rapidly diminish in proportion to the length of time that such treatment is delayed. Lack of knowledge of these simple facts is a source of great wrong not only to the insane themselves, but to society, as it frequently prevents the seeking of medical aid until concealment is no longer possible, and oftentimes until the disease has progressed to a state of hopeless chronicity.

Moreover, its importance is amply attested by the fact that insanity is a disease which invades all classes of society, and one from which no one can claim exemption; that in effect it is more serious and far-reaching and involves a wider range of interests, whether as regards the welfare and happiness of individuals, of families, or of communities, than any other malady known to mankind. To the individual it involves during its existence a loss of man's highest attribute—reason—and in a large majority of cases a loss of that priceless boon—personal liberty. It also involves a disturbance or destruction of his social and business relations, a loss of control of his property and affairs, and, if the disease happens to take an unhappy form, great mental anguish and distress, amounting in many cases to "a living death" which may endure for many years, and finally death itself. To the family it frequently involves great anxiety and distress and in many instances personal danger; also a removal of the loved one from the family circle to the care of strangers with its attendant expense and possible loss of source of income, if the victim happens to be the head of the family; and finally, it involves the stigma which unfortunately and wrongfully still attaches to families known to be tainted with mental disease. To the community it involves the safety of life and property and an enormous expenditure of public funds for provision for the care and treatment of the dependent insane—the State of New York to-day having more than 30,000 insane persons in custody, with an outlay of $30,000,000 for hospital plants and equipments, and an annual expenditure of more than $6,000,000 for the care and treatment of their inmates.

It has been well said that there is no disease which on its first invasion of the family circle creates a profounder sense of distress and helplessness than that of insanity; nor is there one which is more likely to be mismanaged in the initial stage, the friends of its victim being unable usually to comprehend its importance or even to realize its presence; or, realizing it, they are at a loss to know what course to pursue, and in their stress and anxiety they naturally turn to the family physician for advice and assistance. Then, too, a considerable proportion of cases—especially among the wealthier classes—have to be treated at home for a time, particularly in the early and most important stage of the disease, as regards its curability, while a certain number of cases may properly and safely be treated at home throughout the disease, provided they are in competent medical hands.

It may be said, in passing, that the study of insanity presents nothing that is new or incomprehensible; that its phenomena on the mental side consist largely of modifications of the natural characteristics or tendencies of the individual, whether in the direction of perversion, exaggeration, or diminution of those qualities, these modifications being merely the outward expression or symptom-complex of diseased conditions, functional or organic, of the brain—conditions which are due, directly or indirectly, to moral or physical causes.

*Read at a meeting of the First District Branch, Medical Society of the State of New York, October 27, 1910.

In other words, insanity is a disease or disturbance of the intellectual areas of the brain which is marked by derangement, partial or complete, of the mental faculties; a derangement which manifests itself by a prolonged departure from the methods of thinking, feeling, and acting which were usual to the individual when in a state of mental health.

From this it will be seen that there is no common standard of sanity departure from which constitutes insanity, as otherwise all mankind would be more or less insane, inasmuch as no two individuals think and feel and act precisely alike. Hence no man is insane because he is different mentally from other men. On the contrary, every individual has his own standard of sanity, which may differ widely from that of every other person, and it is only when he differs from himself, when he is departed from his normal mental state, or is in a state of mental alibi, so to speak, or when, in common parlance, he is "out of his mind," that he may be regarded as insane.

Thus it appears that insanity is a relative condition, a comparative state; and that the standard of comparison in each instance is to be found within the individul himself. Hence, as before remarked, a man is insane only when he differs from himself, and in order to declare him so we must exclude all other men from consideration and compare the condition in which we find him at the time of the examination, as indicated by his conduct, manner, and speech, as well as by his physical state—especially as regards the performance of bodily functions, including the state of the circulation, the tongue, skin, pupils, appetite, the state of the bowels, the condition of sleep, motor symptoms, etc., with his normal mental status, as determined by his heredity, his birth, his mental development, disposition and temperament, affections, education, moral sentiments, habits, and environment, in order to determine wherein and to what extent he has departed therefrom. For instance, an individual of so-called excitable temperament may exhibit, from trivial causes, mental exaltation or the opposite, mental depression, which up to a certain degree would be clearly within the range of physiological mentality; whereas, similar manifestations from similar or even widely different causes, on the part of another whose organization, temperament, and mental habits are of a different order, might very properly stamp him as insane. That is to say, two individuals may exhibit substantially similar mental symptoms and one be of sound mind while the other would be a pronounced lunatic.

Such being the case, it becomes of the utmost importance in the diagnosis of insanity, especially in obscure or doubtful cases, to institute a careful comparison of the individual with himself. It is only when the physiological limits are passed and the man enters into a psychopathic state that he may be regarded as insane. Nor is it always possible to say just where mental health ends and mental disease begins, so gradually, in most cases, does the one state merge into the other. Insanity, like most other diseases, does not suddenly enter the system at one door while health departs at the other; and while in rare instances the disease may make a rapid onset, usually its approach is gradual and the prodromal stage, which is aptly termed the stage of alteration, in contradistinction to the later stage of aberration, may cover a period of weeks or months, or even years before the so-called established stage —that is, the stage of actual aberration—is reached.

Etiology.—In our study of the etiology of mental disease we are accustomed to dividing its causes into predisposing and exciting, or remote and immediate, a division which, while it fails in some respects to meet the requirements of scientific exactitude, serves a useful purpose in facilitating the study of this branch of psychiatry.

Under the head of predisposing causes are grouped any and all conditions which tend to weaken the brain and nervous system and thus render it peculiarly susceptible to the influence of so-called exciting causes which would be quite inoperative in individuals of inherent brain stability. Prominent in the group of predisposing causes, which I mention in the order of their importance, are: Heredity, alcoholic excesses, syphilis, drug addiction, epilepsy, head injury, organic disease of the cerebral cortex, etc., while under the head of so-called exciting causes, the name of which is legion, may be mentioned general ill health, mental worry and strain, excesses of all kinds, and especially excesses in what I have sometimes referred to as "the four w's," which I mention in the order of their frequency, namely, wine, women, worry, and work. To these may be added toxemias, starvation, hardship, undue exposure, mental and physical shock, the puerperal state, prolonged lactation, pubescence, the climacteric, etc., etc. In fact, anything which leads to a condition of malnutrition of the brain, whether by direct action upon that organ, or by impairing the quality or quantity of its blood supply, may act as an exciting cause of mental disease. In other words, anything that lowers the general nutrition in one who is predisposed to insanity may induce in him a mental upset. Moreover, some of the factors mentioned under both heads may act in a dual causative capacity, that is, they may act as predisposing causes in the first instance and subsequently become potent as exciting causes.

Respecting the potency of predisposing as compared with the so-called exciting caues of insanity, the study and observation of many thousands of cases have convinced me that only those who are predisposed to mental disease, whether inherited or acquired, succumb to the influences of so-called exciting causes, except in so far as the latter may operate to engender a state of brain malnutrition and thus set in motion hitherto latent inherited conditions or tendencies. In support of this claim attention is called to the fact that substantially every individual at some period of his life is exposed, in many cases repeatedly, to many of the so-called exciting causes of insanity, and yet, despite this fact, we find that sanity is the rule—insanity, the exception. So that, contrary to generally accepted medical opinion, as enunciated in the writings of alienists, I believe that the so-called exciting causes of insanity play a very unimportant part, *per se* in the etiology of this disease.

Let us take, for example, that best understood of all forms of mental disease, paresis, which authorities are wont to attribute in a vast majority of cases to syphilis, excessive venery and other excesses of an exhausting nature, and how rarely we find a victim of this disease whose history, on careful inquiry, fails to disclose the existence of an inherited or acquired psychopathic taint. On the other hand, how few of those within the knowledge of every experienced practitioner who expose themselves recklessly to the conditions which are regarded as most potent in the etiology of paresis, ever fall victim to that disease. Dr. Savage, an

eminent English alienist, who regards psychopathic predisposition as the chief cause of insanity, declares his belief that only a certain number of persons are so constituted that they can become insane.

In the physical causes enumerated in the study of a large number of cases by Dr. William Mabon, Superintendent of the Manhattan State Hospital, it appears that over 40 per cent. were due to alcohol alone, while over 60 per cent. were due to alcohol and other physical causes combined. In considering these cases, it is a fair assumption that the prolonged and excessive indulgence in alcohol acting upon the brain and nervous system had predisposed them to the psychoses to which they finally succumbed. And yet, after all, we must give heredity the place of first importance in the etiology of mental disease.

"Heredity," says Ribot, "is that biological law by which all beings tend to repeat themselves in their descendants; it is for the species what personal identity is for the individual. By it a groundwork remains unchanged amid incessant variations; by it Nature ever copies and imitates herself."

"Hereditary transmission," says Spencer, "displayed alike in all the plants we cultivate, in all the animals we breed, and in the human race, applies not only to physical but to psychical peculiarities."

The ancient proverb that "when the fathers have eaten sour grapes the children's teeth are set on edge," doubtless originated in a recognition of the important part which heredity plays in the development of human affairs.

The transmission from parents to offspring of both physical and mental qualities is a fact of universal observation. It is also true that heredity is of far greater potency than environment in shaping a man's destiny in life. "There is a destiny made for man by his ancestors," says Maudsley, "and no one can elude, were he able to attempt it, the tyranny of his organization."

Under and by virtue of the operation of this law we constantly see instances of men of obscure and humble origin, who, despite the most adverse conditions of environment in early life, rise and take their places among the rulers of the nation.

On the other hand, the heredity of morbid tendencies has been recognized "in all times, in every land and in every nation," almost from the foundation of the science and art of medicine. The idea of hereditary disease found apt expression in the ancient but familiar declaration that the sins of the father shall be visited upon the children even unto the third and fourth generations.

The term heredity as applied to the study of mental disease—the term mental disease being here used in its broadest sense, that is, to include not only insanity proper but all other psychoses, as idiocy, imbecility, and psychopathic states of whatever form or nature—implies an original predisposition to the disease transmitted to children from their parents; and, while it is true that insanity resulting from inherited weakness of the nervous system alone without any apparent exciting cause, is comparatively rare, all competent authorities agree that the hereditary nature of insanity has long been recognized as an established fact in medical science, and that heredity plays a most important part in the etiology of this disease through its actual or potential influence upon the nervous organization, whether the tendency descend from direct or collateral branches of the family tree.

This influence usually manifests itself in the progeny in one of three ways, namely, (1) by congenital absence of mind (idiocy); (2) arrest of mental development in early life before full mental power has been attained (imbecility); or, (3) the development of a psychopathic temperament or insane diathesis which expresses itself in a defective or unstable nervous and mental organization which in turn predisposes the individual to succumb to circumstances in the nature of so-called exciting causes that would not affect a person of innate stable constitution. That is to say, if an individual having a strong hereditary predisposition to insanity and another who inherits no such tendency be subjected to the same or to substantially similar exciting causes, as, for instance, domestic afflictions, loss of fortune, severe mental strain and worry, ill health, childbirth, dissipation, excesses, etc., the former would be likely to suffer a mental breakdown, whereas the latter would not; and while it is true in respect to the transmission of psychopathic tendencies that the ancestral taint may be, and frequently is, transformed in the progeny so as to appear in an entirely different form, or it may remain dormant in the second generation to reappear in a later one, or it may be deflected from the direct line of descent to a collateral branch, it is destined to crop out from time to time in one form or another, until it is finally rendered inert through the attenuating influence of wise intermarriage, or until the family become extinct through the sterilizing effect of degenerative processes going on through generations.

"He who inherits a predisposition to insanity," says Maudsley, "does not necessarily get it from a parent who happens to be insane—no, not even though his father was insane when he was begotten, or though in madness his mother conceived him. He gets it from where his parent got it—from the insane strain in the family stock."

Unfortunately, in the present state of our knowledge, the *modus operandi* of hereditary action is not definitely determined. But we do know to a certainty that the effect of hereditary influence upon the individual is to render his brain unstable, and thereby susceptible to influences, in the nature of so-called exciting causes which would be quite inoperative in individuals of inherent brain stability. In fact, experience has amply shown that the progeny of insane or neurotic ancestry are distinctly more liable to develop mental disease under the ordinary conditions of life than are individuals whose ancestry is devoid of insane or neurotic taint.

An examination, even cursorily, of the published statistics relative to the etiology of insanity, will show them to be of small value, owing to the divergent views of collectors respecting the etiological importance of heredity as a causative factor in mental disease, and also to the great difficulty of obtaining reliable data as to the heredity of families, the friends of insane patients being reluctant, usually, to admit, even to themselves, the existence in the family stock of a psychopathic strain. According to the statistical tables contained in the official reports of hospitals for the insane, the percentage of cases ascribed to hereditary influences varies from 25 to 90, the average for all countries being about 60 per cent. The conclusion to be drawn from these statistics, if accepted, would lead us to greatly underrate the importance of heredity as an etiological factor, whereas the fact is, its im-

portance could scarcely be overrated. In other words, heredity is by far the most important factor with which we have to deal in any consideration of the causation of insanity.

"The tendency of late years," says Mercier, "has been to lay increasing emphasis upon the hereditary factor in the production of insanity, but it is doubtful whether, even yet, the true bearing and significance of this factor have been recognized." Another recent writer* on mental diseases, referring to predisposition, says: "This tendency, although it may sometimes be acquired, is much more frequently born with the individual, so that in the majority of the mentally afflicted we find a directly inherited predisposition to insanity."

In taking the position that substantially all insanity is due either to inherited or acquired predisposition; that is, that it rarely occurs in individuals who are not predisposed thereto, either through hereditary or accidental psychoneurosis, I would by no means imply that every predisposed individual is likely to become insane, even though exposed to exciting causes. On the contrary, many of this class escape through the neutralizing effect of one parent, or through insufficient exposure to exciting causes or through intervention of the law of variation which renders the action of inheritance uncertain. Through the operation of this law the psychopathy of a father or a mother may not appear in the descendants until the third generation is reached; or, out of three children hereditarily predisposed, one, two, or even all three may escape. If it were absolutely certain that every one, who is predisposed to insanity, would develop the disease under the influence of exciting causes, we should have less difficulty in making a satisfactory reply when consulted as to the advisability of such persons entering into marriage contracts, as it would then be our duty to forbid them absolutely.

It should be borne in mind that insanity is rarely due to a single cause, whether predisposing or exciting. If careful investigation to discover the etiological factors be made, it will be found in most cases, when reliable data are obtainable, that there exists a combination of causes, all of which are conducive, directly or indirectly, to cerebral malnutrition, which after all is the immediate exciting cause of all insanities. In other words, any disease or condition which impairs the bodily nutrition or alters unfavorably the quality or quantity of the blood-supply, or which seriously disturbs the normal reflex excitability of the nervous system, is capable of becoming either a predisposing or exciting cause of insanity, especially when it occurs in an individual having a psychotic taint, whether inherited or acquired. This would include in the etiological category all forms of disease whether local or general, acute or chronic, and all manner of functional disorders; and inasmuch as the etiological importance of any of these conditions depends upon their potency in producing malnutrition of the brain, it becomes important to fix in mind at the outset the fundamental fact that insanity of whatever type is directly due to functional or structural derangement of the cortical substance of the brain. Hence, in estimating the relative importance of any class of causes, whether predisposing or exciting, we must take into account the part they play in rendering the brain unstable through its denutrition, and thus preparing it for a mental breakdown. In other words, the functional integrity of the mental faculties depend entirely on the healthful activity of the physical system; hence, there can be no unsoundness of mind, in a medical sense, without unsoundness (disease) of body.

*Berkley.

Finally, while the essential physical substratum of all mental disease is undoubtedly a condition of cerebral malnutrition, or denutrition, hereditary predisposition must be regarded as an etiological factor common to all insanities, no matter what the immediate or exciting causes may be; that is, it may act independently as a causative factor, or it may act in conjunction with what are denominated exciting causes.

Diagnosis.—The significant diagnostic factor to be sought for in the early stage of mental disease is evidence of the prolonged departure to which reference has been made, that is, a change in the mental characteristics of the individual. In fact, any prolonged change in the mental or moral tone of an individual should at once excite suspicion of approaching insanity, especially if he be descended from insane or neurotic stock. The watchful eye of affection is usually quick to discern a deviation from bodily health in a member of the family circle, long perhaps before the occurrence of serious or structural disease, but when foreshadowings of disease begin to appear upon the mental horizon how frequently it occurs that friends and relatives, either through ignorance of their true significance, or through a consciousness of inherited taint and dread of the odium which attaches wrongfully thereto, close their eyes to mental vagaries, absent-mindedness, eccentricities of conduct, and other functional disturbances, mental and physical, which usually mark the approach of mental disease and which should have aroused their anxiety. The histories of many of the chronic insane in custody to-day would reveal the sad fact that in the beginning of their malady these prodromes, these danger signals, were unheeded and the disease allowed to proceed unchecked until it had reached a state of hopeless chronicity.

Prominent among the premonitory symptoms of insanity are disturbances of the bodily functions, morbid emotional manifestations, and alterations in the mental characteristics of the individual. Somatic functional disturbances express themselves in various ways, such as pavor nocturnus, insomnia, headache, tinnitus, vertigo, fibrillary tremors, clammy extremities, and other vasomotor disturbances; anorexia, indigestion, constipation, etc. It should be said in passing that while these phenomena, especially insomnia and constipation, are frequently observed in the prodromal stage, they may, one or all, occur in persons who never become insane; hence, they are not to be regarded as pathognomonic, nor singly, perhaps, as even diagnostic signs of mental disease.

If the tendency is to mental exaltation, or mania, the emotional changes usually take the form of unnatural buoyancy, loquacity, undue levity, and morbidly quickened mental operations, the patient frequently appearing to be unnaturally bright. If the tendency is to mental depression, or melancholia, there are gloomy forebodings, morbid introspection, hyperconscientiousness, senseless self-condemnation, a morbid aversion to friends, morbid suspiciousness, irritability, and frequently a vague sense of impending evil of some kind. Marked alterations of character are seldom wanting in this stage of the disease. Thus, for instance, the devout person may become profane; the refined, immodest

and disregardful of the proprieties and decencies of life; the staid individual, becomes capricious and vacillating; the sociable, unsociable; the good-tempered, irascible; the industrious, indolent; the temperate, intemperate; the cheerful, sullen and morose, and the level-headed, conservative business man embarks in senseless enterprises. These symptoms, being in striking contrast to the individual's normal mental status, are indicative of a departure therefrom, and when observed they should always excite suspicion of impending insanity; and while they may vary as regards number, order of occurrence, and intensity, their presence is always significant as danger signals, especially when they occur in persons who are predisposed to mental disease by reason of inheritance, neurotic diathesis, previous attacks of insanity, head injury, alcoholism, drug addiction, syphilis, mental shock, prolonged mental strain and worry, general ill health, etc.

In connection with the subject of the diagnosis of insanity, it should be borne in mind, as already intimated, that the range of normal mental action is by no means a narrow one. That is to say, the mental operations of the brain may be disturbed temporarily by causes of a transient nature, such as variations in the quality or quantity of the blood supply, overwork, excessive emotional excitement, reflex irritations, etc., and yet not transcend the limit of physiological mentality. For instance, if a man under the influence of wine, or on the receipt of exceedingly good news, should exhibit signs of mental exaltation quite unusual to him we would not call it mania; or, if he evinced mental depression on account of bad news or misfortune, we would not call it melancholia. It is only when the physiological limitation is passed and the individual enters into a pathological state, mentally, that we may consider him insane. In other words, whenever an individual is found to have undergone a *prolonged* departure from his normal mental state and the departure is unexplainable on any other grounds, such as drunkenness, delirium, the effects of narcotic drugs or other toxic agencies, a diagnosis of insanity will usually be warranted. Alcoholic intoxication and delirium tremens do not constitute insanity in a medical sense, although the law recognizes the latter as an excuse for crime, and some writers have classed it among the toxic insanities.

It should also be borne in mind, in the diagnosis of insanity, that the patient's statements regarding himself are often unreliable and misleading, owing to delusional ideas or misinterpretation of what actually took place, even though in other respects he may be perfectly truthful. Again, the truth or falsity of certain statements made by the insane can only be determined by evidence from other sources; hence, we should not regard every unusual or extraordinary declaration of a patient as indicative of delusion. For instance, a man may assert that he is the victim of a conspiracy or that his wife is unfaithful to him; or a woman, that she is pregnant, all of which may be true or it may be delusion, so that before determining the diagnostic value of such declarations, corroborative evidence should be sought for from sources other than the patient himself, as by so doing we may avoid the humiliating predicament in which a medical friend of mine once found himself through certifying that an allegation of pregnancy made by a young woman was an insane delusion, when she was in fact pregnant, as an examination would have disclosed, had he taken the precaution to make one.

On the other hand, many of the delusions and hallucinations expressed by the insane are so manifestly irrational as to need no further corroboration, as, for instance, when a man declares that he is a king or the Saviour, or that his legs are made of glass and he refuses to walk lest he may break them; or a woman that she is the Virgin Mary, or a queen, or an empress, etc. Again, we occasionally meet insane persons who are capable of concealing their delusions for a time, realizing that the exhibition of them may result in their being declared insane and deprived of liberty and the control of their affairs; but the deception in such cases rarely fails of detection at the hands of a skilled observer, if time and suitable opportunity for observation be had. Dangerous patients, suicidal and homicidal cases, frequently endeavor to conceal their intentions and their delusions relating thereto; and while cases are occasionally met in which for the time being the most careful scrutiny fails to disclose the existence of any definite or verbally expressed delusion, I have yet to find a case of insanity proper that did not at some stage of its progress reveal the presence of delusion or a *delusional state*, as evinced by the declarations, manner, or conduct of the individual. It need scarcely be said that the most common delusion among the insane is that they are not insane.

In the diagnosis of insanity it is important to take into account certain negative symptoms, as reticence, obstinacy, sullenness, or stupidity, any of which may be significant with reference to diagnosis, especially if such condition is not natural to the individual. Note should be taken also of the facial expression; the contrast in facial expression in mania and melancholia is in itself a lesson in diagnosis, the expression of the eyes and their pupillary reactions to light and accommodation, the speech, writings, motor functions, reflexes, etc., any of which may in themselves be indicative of certain forms of mental disease. The pulse and temperature should also be observed, as persons laboring under the delirium of fever, meningitis, etc., have occasionally been committed to institutions for the insane through inattention to these points.

Other conditions which have been mistaken for insanity are prolonged intoxication, delirium tremens, the delirium of cerebral meningitis, and of the various continued fevers, sunstroke, hysteria, and the delirium which sometimes precedes death in certain diseases and in old age. Most frequent among the prodromes of mental disease are insomnia and constipation. In fact, so common are these symptoms in the onset of acute insanity that the experienced observer comes to anticipate their presence, and to expect an affirmative answer to his interrogations respecting them in substantially every case that comes before him.

Thus I have attempted to portray briefly the most frequent and most important mental and physical indications of the onset of mental disease. These indications may not present themselves in the order mentioned, nor will all of them be observed in every case, but more or less of them will be found in most cases if carefully sought for, and the physician must be prepared to recognize and define the particular departure from the normal state so distinctly and clearly as to satisfy himself and the friends of the patient that the deviation actually exists and that the case has reached a point at which the good of the patient and the welfare of the family and of the community render medical interference imperative.

It is doubtless true that an impending attack of acute insanity could frequently be warded off if the prodromes, which I have characterized as danger signals, were promptly recognized and timely measures for their relief applied. Prevention is better than cure, and to recognize mental disorder in its incipiency will often enable us to adopt remedial measures at the most opportune time for arresting its progress.

The importance of promptly instituting measures for the relief of insomnic states whenever met with in practice, and particularly if the insomnia, as frequently happens, is associated with slight mental depression and constipation, can scarcely be overestimated. The insomnic habit, like many other habits, is easily acquired, and if allowed to go unchecked tends to produce brain malnutrition and consequent mental disease, especially in individuals who are predisposed thereto.

In conclusion it need hardly be said that in view of the fact that every physician in active practice is liable to, and doubtless does, meet cases of mental disease from time to time, it is important that he should possess at least such a practical knowledge of the subject as will enable him to recognize cases when he meets them in practice and to care for them, at least until such time as they can be committed to a hospital for the insane, as a majority of cases of the dependent insane must be.

15 East Forty-eighth Street.

PELLAGRA;

A BRIEF REVIEW OF THE THEORIES OF ITS CAUSATION, WITH THE REPORT OF A CASE OCCURRING IN NEW YORK CITY.

By JOSEPH COLLINS, M.D.,

NEW YORK.

ATTENDING PHYSICIAN TO THE CITY HOSPITAL,

AND

LUTHER SHELDON, Jr., A.B., M.D.,

RESIDENT PHYSICIAN IN THE CITY HOSPITAL.

Pellagra is the name given to a chronic disease affecting the rural population of countries in which Indian corn or maize forms a staple article of diet. A fungus, living as a parasite on this widespread food plant, which nourishes millions of inhabitants of the old and new world, is almost universally assumed to be the causative factor of the disease. It is reputed to be assisted in its nefarious work by unfavorable hygienic conditions and prolonged exposure to the sun. For this reason pellagra is known among Italian writers as "Malattia della miseria." Pellagra has also been referred to protozoa, and stinging insects have been held responsible as the carriers of infection. Many writers do not consider pellagra as a uniform disease, holding that several different cachexias due to malnutrition present the same symptoms.

The disease usually appears in the spring and autumn, and runs a protracted course with periodic exacerbations and remissions, the former occurring mostly in the spring. The average age of the patients is between twenty and fifty years. The clinical picture of pellagra is confusing and complicated, because disorder of the skin, the digestive apparatus, and the nervous system all participate in the symptom complex. Increasing erythema of the exposed skin develops and gradually leads to cutaneous thickening with pigmentation and exfoliation. The characteristic erythema has been seen in individuals who have been confined for years in insane asylums and who have not partaken of maize for a long time.

The nervous symptoms of pellagra may take the course of a psychosis with progressive dementia, or they may suggest a chronic degenerative disease of the spinal cord. A very common and characteristic symptom consists of extreme muscular weakness. If left untreated, the disease runs on to death, sometimes extending over years, up to fifteen, under continued chronic cachexia and marasmus, often with extreme emaciation. In many cases the psychic depression of the patients constitutes a chronic insanity. There is a peculiar tendency to commit suicide by drowning. In pellagrous countries about 10 per cent. of the patients are confined in institutions for the insane.

In the early days of pellagra, about 150 years ago and about 200 years after Indian corn had been introduced into southern Europe as a food, much work was done with a view of ascertaining the etiological factor in the disease. Many interesting

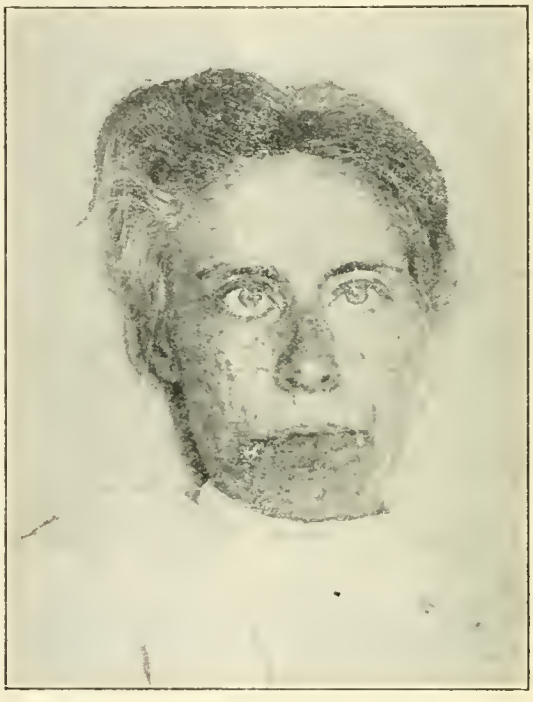

Fig. 1.

hypotheses were advanced, among them being the belief that pellagra was a degenerative form of leprosy; that it was a manifestation of syphilis; and that it was not a true disease at all, but that it was a symptom complex brought about by various autointoxications.

It was not until 1776 that corn was seriously considered as playing an important rôle in the disease. At this time in Venice the sale of damaged corn was prohibited because pellagra had spread to such a marked extent among the users of this corn. Ballardini in 1845 made the statement that pellagra was caused by eating damaged corn. Since this time the controversy has continued with unabated energy until now we find two schools among those who have studied the disease carefully: (1) Those who believe corn to be the undoubted etiological factor and (2) those who deny this. As yet, however, those of the first school have been unable to reach any agreement among themselves as to what there is in corn that would cause the

disease. Many fungi and moulds have been described as the essential cause, also many bacteria which are often found upon corn, especially when it has been damaged by long standing or improper care. The second school is no more agreed than the first, but most of its followers believe that the disease is protozoal in origin.

At the present time the believers in corn as an etiological factor seem to have the better of the argument, and all recent investigation tends to prove this more clearly. Still, even now, the ultimate cause of pellagra is almost as much in doubt as ever, for, although corn may be conceded to play some part, what part it plays is not known.

Again, it has never been clearly shown how the various cardinal symptoms of pellagra are produced, nor why there is a tendency for the disease to recur at certain seasons of the year. J. D. Long of the U. S. Public Health and Marine Hospital Service has attempted to explain this latter phenomenon on the grounds that during the "pellagra season," that is, the months of March, April, and May and September, October, and November, there are more sudden changes in temperature than at

Fig. 2.

other seasons of the year. In the absence of any other explanation, this must be accepted as the true one.

H. D. King of New Orleans showed that the sun played some part in the distribution of the skin lesions, as had long been believed. He proved this by having his patients expose other parts of the body to the sun than those usually affected, with the result that skin lesions appeared on the parts so exposed.

Pellagra is most often a chronic disease running a course of several years with remissions and recurrences, the recurrences usually appearing during the "pellagra season" above referred to. The mental condition of the patients is usually worse in each succeeding attack, although occasionally there are cases in which the later attacks are less severe than the earlier ones. Still more rarely the patients may go for a number of years without a recurrence or may be permanently cured.

In regard to the treatment of pellagra but little has been accomplished, which is but natural when it is recalled that the cause of the disease is still very much in doubt. No treatment has proved satisfactory, for many cases have died in spite of all treatment and some have recovered with no treatment at all. Cole and Winthrop of Mobile, Ala. (*Journal of the A. M. A.*, April 23, 1910), have reported a series of eleven cases in which transfusion of blood, preferably from recovered pellagrins, but where this could not be obtained, from relatives of the patients, who apparently have led the same kind of life as the patients and who might be thought to have a natural immunity since they have not acquired the disease, has been tried. Of the eleven cases so treated six were apparently cured and five died. As all of these cases were of the advanced type, the results seem to call for further investigation along this line. Others have tried injections of serum from horses recovered from "blind staggers," the idea being that pellagra and "blind staggers" are similar conditions and both caused by eating diseased corn. Still others have used preparations of arsenic, of quinine, of iron, strychnine and so on through the entire Pharmacopeia without arriving at any definite conclusions as to the value of any drug. In fact, no drug seems to be effective, hygiene and proper feeding alone accomplishing as much as, and no more than, the same combined with the use of many drugs. It seems hopeless to try to accomplish much in the way of treatment until the true etiological factor in the disease is found.

The acute cases, by which we mean those which are rapidly progressive and which are fatal in the first attack, are still comparatively rare. It is extremely unusual for such a case to find its way into a general hospital and there to be observed during the entire course of the disease. Therefore we feel that we are justified in reporting the history and findings, both ante-mortem and post-mortem, of such a case which was in the wards of the City Hospital during almost the entire course of the disease. This case is especially interesting in that the patient has practically never been outside of New York State and that the disease made its first appearance after seven consecutive years' residence in New York City.

The patient, a woman, aged 41 years, unmarried, entered the City Hospital March 21, 1910, complaining of pain about the rectum, pain in calves of legs, nausea, vomiting, and diarrhea. Examination at this time showed extensive areas of excoriation about the anus and vulva; red, swollen and tender labia majora; and a thick creamy discharge from the vagina. Her hands were covered with a brownish discoloration, on top of which were fine, dry scales.

As her principal trouble was with her external genitalia and as she was obviously in need of local treatment, she was sent to the genitourinary ward and remained there until the last of April, when she was transferred to the medical ward for treatment of a severe gastritis and enteritis, presumably due to chronic alcoholism. The patient remained in this ward until July with practically no change in her condition except for a spread of the area of discoloration on her hands. On the 1st of July she came under our observation and at this time gave the following history: She was born in Utica, N. Y., 41 years ago; she went early to Chicago, remained there two years, and then removed to Syracuse, N. Y., remaining there until seven years ago, when she came to New York City. She has always lived in the more thickly settled districts of the city, never in the country. As a child she had the usual diseases, but was otherwise of good health. She

was always of an extremely nervous disposition. Six years ago she was in a hospital for three months on account of inflammatory rheumatism. Some years ago she had typhoid fever. She had always had throat trouble during winter months. During the winter of 1909 her appetite had been very poor, sleep poor, and bowels very irregular. For past seven years she has been a heavy, steady drinker of whiskey. Four months ago she was operated upon for peritonitis and one ovary was removed. She denied venereal infection.

Since coming to New York, seven years ago, the patient has worked as a saleswoman except for past two years, during which time she has been employed as a waitress in restaurants. She has never been a steady user of cornbread, nor of corn in any form. When living in Syracuse all bread eaten by patient and her family came from one bakery and cornbread was eaten not oftener than once in two weeks. Except for this patient denies ever having eaten cornmeal in any form. Menstruation began at 14; never regular, and always excessive in amount. The patient has not yet reached the menopause.

The present illness began in March, 1910, with pain about the anus, more marked on defecation. The throat had been sore all winter, but became much worse at this time. Tongue very painful, especially on inferior surface. Has had headache, loss of appetite, nausea, pain on swallowing, and pain in the abdomen. Has been suffering from profuse vaginal discharge since entering the hospital. Hands and arms are at times intensely "itchy" and have been inflamed since March.

The patient's condition at this time was as follows: Patient is somewhat emaciated. Is unable to leave bed. Her expression is one of stupidity, with occasionally a fleeting look of suffering. Her mind is at times clear, while at other times it wanders and patient becomes much confused, especially as to time and place. She also has occasional spells of crying with no apparent cause. The diarrhea is almost continuous and the stools are watery and have a very foul, "coppery" odor. At times patient is incontinent of both urine and feces. There is a very severe stomatitis of which patient complains a great deal. The dorsum and edges of the tongue appear bright red and have a raw appearance, while the inferior surface shows several small ulcerated areas, grayish in color. These are very painful to touch. On the skin about the mouth are areas of dry, brownish-yellow crusts on a red, rough base, not indurated. These are most marked at angles of lips. Teeth are covered with sordes. On the dorsum of each hand and extending over backs of fingers and up the forearm about 8 inches on the extensor surface and 3 inches on flexor surface, is an irregularly shaped, diffuse, uniform eruption consisting of fine, dry scales and crusts on a markedly erythematous base. The margins of the eruption are sharply defined, slightly raised, and red, and are apparently of more recent origin than the remainder of the eruption. Over the olecranon process of each elbow is a somewhat similar area slightly darker in color. There is also a similar eruption on the anterior axillary fold of the left side. These areas are not painful, but at times itch and burn considerably. About the external genitalia and extending into vagina are excoriated, swollen, and painful areas. Pupils react promptly to light and in accommodation. Right pupil slightly larger than left. Biceps jerks exaggerated, as are also the knee jerks, the right more so than the left. No patellar nor ankle clonus. There is distinct Babinski phenomenon on the left. No evident sensory disturbance. Heart and lungs negative. Abdomen negative except for a fairly well marked tenderness over entire abdomen.

The laboratory findings were: *Urine*—Large quantities, straw color, acid, Sp. G. 1014, faint trace of albumin, no sugar, many hyaline and few granular casts. *Feces*—Greenish-brown, watery stool, with a foul, "coppery" odor. No parasites nor ova found. No blood. *Blood*—Red cells, 4,090,000; white cells, 10,400. Hb., 85 per cent.; polynuclears, 68 per cent.; large lymphocytes, 16 per cent.; small lymphocytes, 15 per cent.; eosinophiles, 1 per cent.

On July 6 there appeared on patient's back, at level of second dorsal vertebra, a large furuncle. On July 16 a similar furuncle appeared just below this. Smears and cultures from these showed pure cultures of staphylococcus. Except for a few days following the appearance of the furuncles the patient's temperature was normal throughout the course of the disease.

On July 20 the patient was apparently improving save in her mental condition. Under local treatment the scaliness and crust formation on the hands and forearms diminished, and with these the pruritus. The hands and forearms were distinctly erythematous. The stomatitis under applications of chromic acid had become less painful and the breath less fetid. Large doses of bismuth had checked, to a large extent, the profuse diarrhea, although this was still present in a less marked degree. The patient's mental condition had become progressively worse. Her fits of depression were more frequent and of longer duration and she was almost completely disoriented for time and place.

On July 23 the patient passed into a condition of continuous stupor with marked carphalogia and low, muttering delirium. She could not be aroused from this coma and remained in this condition until July 25, when she died. One week before death the patient's hair began to turn very gray and at the time of death was entirely so.

The diagnosis of pellagra had been made despite the absence of a history of continued corn eating and a history of previous attacks in view of the fact that the patient presented the following well-known cardinal symptoms of pellagra:

1. Symmetrical erythematous eruption on the dorsum of the hands and on the extensor surface of the forearms. 2. Chronic profuse diarrhea. 3. Very marked stomatitis. 4. Progressive mental deterioration. 5. Abnormal reflexes.

If diseased corn is thought to be the cause of the disease this case plainly shows that only small quantities of damaged corn are necessary to produce pellagra, and that the harmful effects of the corn may remain latent for a period of at least seven years, this being the time which had elapsed since the patient last had eaten corn and the appearance of her symptoms.

We are indebted to Dr. L. S. Milne of the Russell Sage Institute of Pathology for the following report of the autopsy findings in this case: "The body was that of a very emaciated woman apparently about 50 years of age. The autopsy was conducted 56 hours after death, but the body was in good condition. There was slight edema of the lower part of both lower extremities and well marked protruberant external hemorrhoids. The skin of the anterior axillary folds, especially on the

left side, also upon the posterior surface of both elbows and the dorsum of the hands and wrists on both sides was affected by a chronic cornified dermatitis. On microscopical examination the skin in these situations showed an extensive thickening of the stratum corneum and some hyperplasia of the deep layer. The subcutaneous tissue also in these affected areas showed some slight subacute inflammatory process. Over the vertebra prominens there was a deep trophic ulcer and close to the spine, on the right side of the middorsal region, were two small similar ulcers. There was no fluid in either pleural cavity nor in the pericardium, nor was there any evidence of acute or chronic inflammation in these serous sacs.

The lungs were emphysematous and edematous throughout. The bronchial glands were slightly enlarged and pigmented, but like the lungs, showed no evidence of tuberculosis. The bronchi were congested and the mucous membrane atrophic from chronic bronchitis. The base of the tongue showed a slight lymphoid hyperplasia, but no smooth atrophy. The thymus and thyroid showed no important change. The heart weighed 300 gms., was atrophic, soft, and flabby. The tricuspid orifice measured 11 cm. in circumference, the mitral 12 cm. The valve segments were all in good condition. There was no atheroma of the aorta or coronary arteries.

On opening the abdominal cavity there were found numerous old adhesions between the intestines and the uterus and adnexa. The uterus itself was retroflexed and atrophic and its interior showed an old chronic endometritis. The intestines showed no important changes nor did the lymph tissues appear grossly hyperplastic. Microscopically, in the large intestine there were some evidences of a chronic catarrhal process and some slight lymphoid hyperplasia. The liver weighed 1,700 gms., was soft and pale yellow in color. It presented the appearance of an old standing venous stasis and a more recent acute degenerative fatty change. Microscopically, this fatty change was very evident, the liver cells at the periphery of the lobule being especially affected. There also appeared to be a considerable degree of liver-cell multiplication, presumably a compensatory process following the liver-cell destruction. The gall bladder was filled with dark orange, very fluid bile, but no gallstones.

The pancreas was small and its lobules somewhat atrophic, and, on microscopical examination, showed no important change. The spleen weighed 300 gms., was slightly enlarged and its Malpighian bodies slightly hyperplastic. The condition of the organ was one of old standing stasis with superadded subacute reactive change. The kidneys (left, 200 gms.; right, 175 gms.) showed evidence of old standing venous congestion with also some recent cloudy and fatty process. There were no signs of chronic nephritis.

The membranes of the brain showed no important changes. The dura was not adherent. The subarachnoid space was considerably distended with fluid. The convolutions of the cerebrum showed no abnormality. The vessels of the base of the brain were well preserved. The interior of the cerebrum, crura, pons, and medulla presented no gross lesion other than a moderate amount of edema. Microscopically, in various parts of the cerebral cortex, particularly in the frontal region, the nerve cells, particularly of the deeper layers, showed some atrophy and excessive pigmentation. The small vessels in the cerebral cortex were well preserved and there was no evidence of any chronic inflammatory process. The membranes of the spinal cord showed no special change. The cord presented no gross nor microscopical abnormalities, the posterior and lateral columns showing no degeneration. The cells of the anterior horns were quite normal, and the most careful scrutiny failed to reveal any change in the white matter that could be construed to be a sclerosis. The sciatic nerve showed no microscopical change. Sections of the median, musculospiral, ulnar, and both popliteal nerves, particularly the external, showed a patchy degeneration of the nerve fibrils without any chronic inflammatory process, and presenting the common picture observed in cases of alcoholic neuritis.

As a summary of this case, practically nothing positive as regards pellagra could be determined. There were definite evidences of some subacute toxic process which may have been responsible for the condition of the nerves and the degenerate state of the cortical cells in the cerebrum, yet these conditions could not be isolated from a possible alcoholic process.

In this case, as has been seen, no positive evidence of pellagra was found at autopsy. Unfortunately, this has been true in every case which has been reported with autopsy findings, the findings varying in every case. However, it seems reasonable to suppose that the changes in the peripheral nerves may have been at least partly due to the pellagra itself. It also seems probable that had this patient lived longer the changes in the brain and cord which have often been described as being typical of pellagra would have developed later, but it seems to me very questionable that pellagra causes true symptomatic disease of the central nervous system.

Summary of the Morbid Changes in the Nervous System Usually Found After Death.—The microscopical examination of the nervous system in three cases reported by Lukáse and Fabinyi[1] showed the changes to be analogous with those which can be experimentally produced by poisoning with ergotin, mercury, and aconite. The brain and spinal cord show vascular and cellular changes, pigment degeneration of ganglion cells, various retrogressive processes. The findings in the spinal cord consist in combined strand scleroses, most frequently in posterior and pyramidal lateral sclerosis (Tuczek[2]). According to reported autopsy findings the nerve cells in the brain were disintegrated chiefly in the deeper layers, mostly so in the central convolutions; whereas the subcortical ganglia and the cerebellum were fairly free. In the medulla oblongata the motor cells were chiefly attacked, the changes increasing in severity toward the spinal cord.

The changes of the neurofibrils in the cells of the central nervous system, in pellagra, were studied by Parhon and Papinian,[3] who demonstrated atrophy up to complete disappearance of the fibrils; especially well marked in the Betz pyramids from the large anterior horn cells. Parallel with these changes are atrophy of the nucleus and modifications of Nissl's plates.

Remarks on Some of the Nervous Symptoms of Pellagra.—With special reference to the nervous symptoms of pellagra the clinical picture may suggest syringomyelia, also tabes and paralysis agitans. The symptoms of ataxic paraplegia may manifest themselves on the basis of a combined degeneration of the posterior and lateral columns, sometimes also

the anterior horn of the spinal cord. The lateral column symptoms occupy the foreground of the spinal phenomena. The most common condition is paresis, with spasticity and increased tendon reflexes. The posterior column symptoms are not well developed, as a rule. The degeneration of the posterior columns in pellagra differs from that of tabes by the relative immunity of the posterior roots, Lissauer's boundary zone, and the gray substance (Tuczek).

There is no specific pellagra psychosis. The nervous symptoms of pellagra, which are referable to intoxication of the nervous system (cerebral, spinal, and sympathetic), are, in the first place, functional in character, only gradually assuming the marks of an organic affection; marked remissions are still possible in regard to the psychic as well as the spinal and peripheral manifestations. The disease is characterized by the very slowly progressive character of its symptoms, notably the dementia which is usually not severe. The combined psychic symptoms generally resemble those of presenile involution with hypochondriacal delusions. Youthful patients often present all the psychic hallucinations of involution melancholia.

An Italian writer, Vedrani, points out the resemblance of pellagra psychoses to the disturbances caused by alcohol; conditions closing resembling delirium tremens are not at all uncommon.

As sufferers from "psychoneurosis maidica" 3,000 of about 100,000 Italians affected with pellagra are confined in insane asylums (Sambon). These figures intimate more eloquently than words the potential danger to this country, notably the Southern States, from what De Jarnett graphically names the corn curse (Thirteenth Annual Report of the State Board of Health of South Carolina for the fiscal year 1909).

The prevalence of the disease in many corn-consuming countries is not generally realized. In his remarks on the geographical distribution of pellagra, Sambon points out that the disease occurs not only in Italy, Spain, France, Roumania, Korfu, northern Portugal, the Tyrol, Dalmatia, Croatia, Bosnia, Turkey, Greece, Bessarabia and Poland, but also in Lower Egypt, Algeria, Tunis, on the Red Sea, in southern Africa, Asia Minor, India, Mexico, Brazil, Argentina, the West Indies, and New Caledonia. VENTILATION OF KITCHENS AND BAKERIES.

By W. A. EVANS, M.S., M.D., LL.D.,
CHICAGO,
COMMISSIONER OF HEALTH, CHICAGO; PROFESSOR OF HYGIENE, NORTHWESTERN UNIVERSITY MEDICAL SCHOOL.

The ventilation principles elsewhere discussed apply to kitchens and bakeries. In consequence they will not be repeated here. This discussion will be limited to those factors which distinguish the ventilation of kitchens and bakeries from that of ordinary rooms.

The kitchens of domestic households do not require much space in this discussion. Such kitchens are usually occupied by but one or two persons. The occupation is intermittent. Generally the kitchens are well lighted and have plenty of window space for ventilation. Things are very clean. Among the poor the kitchen usually serves as a laundry and sometimes as the day living room, and not infrequently it is occupied by one or more beds at night. Such an arrangement is good neither for the food nor for the people.

This article, however, will be limited to a discussion of conditions in the kitchens of restaurants, hotels, and lunch counters, and bakeries run in connection with these or as exclusive bakeries. These kitchens and bakeries are generally overcrowded. They are usually dirty; they are hot, humid, and their air is high in CO_2.

The people who occupy them work long hours in the same environment and for about two hours twice a day, and occasionally three, the work is done rapidly and under tension. In the case of bakeries there is a period of work during the dough mixing, followed by some slack hours, and then a period of work during the baking. During the rest period the custom often is for the workers, or some of them, to get some sleep in the bakery.

In the kitchens the dishwashers and under helpers are very apt to be people with low standards of cleanliness.

In consequence of these several items, the workers are prone to develop pneumonia, consumption, asthma, colds, rheumatism, headaches, pallor, languor, and susceptibility to infection. The food produced in such places is not influenced as much by the environment as are the people who produce it. Esthetically it would not appeal to the consumer if he could see where and how the food is produced.

In the city of Chicago the cheap women's cooperative lunch clubs usually produce food in inviting surroundings and in an inviting way. Some of the large industrial establishments providing cheap lunches as a sociological endeavor likewise produce well. Most of the department stores have inviting kitchens.

But if the general run of people who patronize hotel, restaurant, and lunch rooms, and who at home eat food produced in immaculate, sunlighted, ventilated kitchens could see the places in which food is produced eating would be diminished, a reef would be taken in the general tendency to obesity. Besides, what right has a man or woman to patronize such places and by that support force poor or ignorant Bohemian, Polish, Irish, and German men and women to work in places that will probably be their undoing in a few years? If they drift in four or five years to the consumption hospital, or in six to twelve months to the pneumonia ward in the county hospital, are not the patrons of such kitchens and bakeries in some measure to blame?

Kitchens in the places mentioned are usually greatly overcrowded. In them are located the cooking stoves and the bake ovens, the hot food tables, the refrigerators, the dough-mixing troughs, the dishwashing machinery, the laundry for the linen, the meat cutting space, the fowl, fish, and small-animal cleaning space, the potato paring, and other vegetable and fruit preparations, the dressing rooms for the help, the lockers, the washing rooms and toilets, and the waiters' assembly tables. The rule, to which there are but few exceptions, is that things are so jammed together that cleanliness and good sanitation are impossible.

The first requisite for a sanitary kitchen is to get more room; to take certain things out of the kitchen, *i. e.* the laundry work, the dressing rooms, the lockers, the toilets, the fish, fowl, and small-animal cleaning, and the preparation of potatoes, cabbage, lettuce, and other vegetables and foods making much waste and litter. When this is accomplished much of the dirt can be eliminated.

The second thing is to get good air. The air in kitchens and bakeries is hot and humid. The heating agencies are greater than the cooling. The temperature in all parts of the room is more than 80° and in places it goes well over a hundred. Therefore the foul air cannot be taken out satisfactorily except at the ceiling. Satisfactory results can never follow any effort to pull this hot air down to the floor line.

The men in the room are working under pressure and in great heat. They will not tolerate the entrance into the room of air which has not been previously heated. Therefore the air for kitchen and bakery ventilation in cold weather must be heated air. It should be heated to 55° to 60°. This can be done in several ways. In case there is radiation in the room, the radiators can be placed before the windows or in front of other inlet ducts so that the entering air is heated as it enters the room. Often it will be possible to use the excess heat from the bakery and kitchen fires and the hot, outgoing air to heat the incoming air. This can be done by such an arrangement of the ducts that the outgoing ducts parallel or encircle the incoming ducts.

The principles then are: (1) Direct upward removal of the heated, foul air. (2) The introduction of partially warmed, fresh air into the room, entering near the floor line.

It is customary to have hoods directly over the hot table for the purpose of direct removal of the food odors and to prevent their escape into the adjacent dining rooms or into other parts of the house. This is a wise provision. The same provision should be applied to the heat, humidity, and CO_2 which are more harmful though less manifest.

The cooking operations make a kitchen abnormally humid. A bakery is less so. The principles laid down for heat and odors apply with equal force to humidity. The standards of ventilation of a kitchen or bakery should be the temperature and the humidity.

Kitchens and bakeries should always be above ground. Cellars are shielded against external atmospheric conditions. If the air is hot cellars remain cool because the external heat is not imparted to them. If, on the other hand, heat is being made in the cellar, the cellar gets exceptionally hot. Nothing so impresses on us the importance of window and wall radiation and conduction of heat and leakage of air as does the different air and temperature behavior of cellars where these factors are in abeyance. It would seem that cellars would offer a most excellent opportunity for the development of a direct removal system of ventilation with the minimum of disturbance from cross currents. Certain work should therefore be permissible in basements, but they are not places for anything in which there is great heat production, coupled with great humidity.

In addition to these factors, sunlight is needed in bakeries and in kitchens. Where there is as much dust as there is in a bakery and as much dirt as there is in a commercial kitchen, sunlight is needed for two reasons: First, the light shows where the dirt is and forces greater efforts at cleanliness. Second, the sun's rays are needed to kill the bacterial life on the floors, walls, shelves, pans, and pots.

SURGICAL ANATOMY OF THE ABDOMINAL WALL WITH REFERENCE TO APPENDECTOMY.

By WALTER E. TOBIE, M.D.,

PORTLAND, ME.

PROFESSOR OF ANATOMY, MEDICAL SCHOOL OF MAINE; ASSOCIATE SURGEON MAINE GENERAL HOSPITAL.

The abdominal wall presents an interesting study in embryology. It is a region where we may demonstrate all of the segmental features of vertebrate anatomy. Reduced to fairly simple terms, it may be considered a cylinder composed of a number of rings piled one upon another and fused together. Each ring is, morphologically, the development of a mesodermic somite and contains, dorsally, a bone. Laterally and ventrally, it is a fibromuscular layer in the substance of which a nerve, artery, and vein course forward on each side. During the growth of the embryo the muscular portions of the mesodermic somites (known as myotomes or muscle cuts) undergo numerous changes. They all spread forward to enclose the body cavity and fuse together. The result would be a continuous sheet of muscle fibres were it not for additional changes by which the sheet is split longitudinally and tangentally with fibrous interlayers, prolongations and septa. In addition to these changes there are alterations in the direction pursued by the muscle fibres so that some are directed longitudinally, some transversely, and some obliquely upward and forward and downward and forward. The rectus abdominis gives a clearer idea of the segmented arrangement of the embryo than any other muscle in the region. It represents the entire thickness of the ventral ends of six or seven myotomes which are, of course, supplied by as many nerves. Its fibres pursue the original direction of the fibres of the myotomes and the muscle belly is broken up by tendinous inscriptions into a number of segments. These segments are not, however, as numerous as the number of myotomes from which the muscle is derived, several of the segments having fused completely without the intervention of fibrous inscriptions.

In the anterolateral abdominal wall the nerve of a mesodermic somite is best represented by an intercostal or ventral primary division of a thoracic nerve and its artery by an aortic intercostal or lumbar, with corresponding veins. The nerves in this region preserve through all the developmental changes their relative position and importance. The arteries maintain something of their primitive position, but suffer in importance by the greater growth and extension of other and newer arterial outshoots. The transverse arterial plan prevails dorsally and somewhat laterally, but ventrally the principal trunks pursue a longitudinal direction, as do also the largest veins.

To open into the abdominal cavity we have then to cut through a fibromuscular cylinder, in the walls of which are embedded nerves and blood vessels. The indications are to reach an organ quickly and safely, doing as little violence as possible to the structures through which we cut. The vegetative integrity of this wall depends upon its nerve and blood supply, its functional activity upon the nerve

supply alone. The mechanical integrity depends to a considerable extent upon the direction of the fibres of both muscular and white fibrous tissues.

There is no artery in the antero-lateral abdominal wall that may not safely be cut, but curiously enough the large arteries are so located that they are not cut in any ordinary operative incision. The operative area is a hexagon, bounded above by the margins of the costal cartilages, below by the iliac and pubic crests, connected by the inguinal ligaments and laterally by imaginary continuations of the mid-axillary lines. Taking a single half of this hexagon we find the superior and deep epigastric arteries at one side of the mid-line of the body, the deep circumflex iliac on the lower line and its ascending branch on the outer side, communicating above with the termination of the musculo-phrenic, which extends from the upper angle along the upper border. Thus we have on each side an anastomosis which may be called a vascular circle, although its outline is four sided. A vertical median cut will come between the epigastrics of the two circles, and McBurney's point is inside of the right circle. There is, of course, a free anastomosis of small arteries inside of these circles and it is also understood that the branches making up the circles are deep branches and are accompanied by companion veins. The superficial arteries are relatively small, but in contrast the superficial veins are rather large. One in particular, the thoracico epigastric, is inside of the circle and is often cut in appendectomies. Its importance is very generally underestimated, and I believe that this is the vein responsible for sudden death from pulmonary embolism after appendicitis operations. Its cut ends should be tied at once. It is apparent that while a knowledge of the distribution of the blood vessels of the abdominal wall is conducive to safe and rapid operating, no desired incision need necessarily be abandoned on account of this knowledge.

The fasciæ and aponeuroses are developed from the myotomes. Being strictly sustentacular, in dealing with them, the problem is practically one of mechanics. The general direction of the fibres of these sheets is transverse. This is particularly noticeable where they ensheath the recti, near the middle of the operative hexagon. At its upper and lower parts they are directed, respectively, inward and somewhat upward and inward and somewhat downward. Fortunately these are also the directions followed by the cleavage lines of the true skin and the nerves of the abdominal wall. These nerves are the lower five intercostals, the sub costal, ilio-hypogastric, and ilio-inguinal. The tenth intercostal follows an almost directly transverse direction in the ventral wall and terminates near the umbilicus. The nerves above and below the tenth diverge gradually from the direction followed by the tenth, so that the lowest and highest run approximately parallel with the lower and upper borders of the hexagon. The importance of these nerves cannot be overestimated. Being sensory, motor, and trophic, they are the functional life of the abdominal wall.

From an anatomical standpoint, then, an ideal abdominal incision must avoid nerves and split between fibres. Both of these requirements are met perfectly in the McBurney incision for appendectomy, where not a structure of importance is injured. With Weir's prolongation or modification it meets about as many contingencies (where the appendix alone is involved) as any single incision. McBurney's incision is too well known and commonly used to require description. Weir's prolongation is less well known and not as much used, although it is based on anatomical principles as correct as those embodied in the McBurney operation. A study of the aponeurosis of the external oblique shows that this structure is not fused with the aponeurosis of the internal oblique at the linea semi-lunaris, but is prolonged over it to the linea alba. Its fibres are obliquely directed and may be split and retracted, showing those of the internal oblique beneath pursuing a transverse direction. To enlarge the McBurney incision by Weir's method then it is only necessary to prolong the split in the aponeurosis of the external oblique toward the mid-line, retract the edges, split the ventral layer of the sheath of the rectus (transversely, of course), retract the rectus toward the mid-line, tie the deep epigastric vessels in two places and between these ligatures cut all the layers dorsal to the rectus transversely. After the removal of the appendix, the various layers are brought together in their natural relations. This incision meets all ordinary requirements and fails only when the appendix is in some unusual position.

An exceedingly ingenious, though little used, incision is that of Gill Wylie. The first cut is made in the usual oblique direction but nearer the mid-line than in the McBurney incision, so that the center of the cut comes a little inside of the linea semi-lunaris. This cut goes through the skin, superficial fascia, and the aponeurosis of the external oblique. A transverse cut is then made through the ventral layer of the sheath of the rectus, the rectus retracted mesially and the posterior layer cut transversely. It will be noticed that muscle fibres are neither cut nor split and that the transverse direction of the incision avoids the nerves. The anatomical principles involved are practically perfect, but the opening gives a limited operative space. For this reason it is by many considered not as good as the McBurney. It may be enlarged outwardly by continuing the split in the aponeurosis of the external oblique, cutting the linea semilunaris and splitting the fibers of the internal oblique and transversalis. The result is the same as that secured by McBurney's incision with Weir's prolongation.

The vertical incision through the outer border of the right rectus is exceedingly popular and has some surgical advantages. Anatomically it is so faulty that one wonders at its use. With the exception of the rectus muscle it cuts across the fibres of every layer through which it passes at an angle of either 45 or 90 degrees. But this is not its only fault. The sheath of the rectus may properly be considered a conjoined tendon of the internal oblique and transversalis muscles with its insertion at the linea alba. A cut across this tendon is necessarily followed by a retraction of its proximal side. Therefore the wound gapes. Nor does the rectus by its contraction tend to produce closure, but rather the reverse, through a buckling action produced by force exerted on the upper and lower angles of the wound pulling them toward each other. Moreover, unless the incision is made short and fortune favors the selection of its site, it will sever one or more motor nerves and destroy the function of a part of the rectus muscle. Accordingly then, instead of urging as one of the advantages of this incision, the fact that it may be lengthened, its description had better be supplemented by the caution, "It should not be lengthened."

The oldest appendectomy incision, and one still employed occasionally, is the oblique incision directly through all the layers at McBurney's point. This incision meets with one important anatomical indication, inasmuch as it ordinarily spares the nerves. The principal objection to it, and a valid one, is that it cuts across the muscle fibres of the internal oblique and transversalis. It is, therefore, mechanically faulty.

The median incision cuts directly across the fibres of the combined aponeuroses, but avoids the nerves, coming as it does between the terminals of the two sides. It has been criticised as involving an area where the blood supply is poor, implying that the reparative process is less perfect here than elsewhere. This objection is more theoretical than real. Practically this incision does not pass through a single blended layer, but through several distinct layers. Below the umbilicus the linea alba is exceedingly narrow and the inner borders of the two recti are in very close apposition. Many surgeons have written and spoken of their own, so-called, peculiar method of incising below the umbilicus, making a special point of cutting to one side of the linea alba and opening the sheath of the rectus. As a matter of fact, it is difficult to do otherwise and the abdomen is seldom opened in the mid-line below the umbilicus without exposing the muscle fibres of one of the recti.

So far I have considered the various incisions from the standpoint of the anatomist with an occasional hint at surgical indications and necessities. While the appendix is usually found near McBurney's point, it may be in many other locations, and better reached by other than the conventional incisions. Errors of development are responsible for some variations in the position of the appendix. Other variations result from adhesions of its tip, consequent upon a long mesenteriolum or an unusually movable cecum. It is not always possible to determine the best operative site by the external signs, and I recall performing two appendectomies one morning where this point was well illustrated. In the first operation I made a relatively high McBurney incision and found the appendix low down near the mid-line. In the other I made a rather low median incision and found that the appendix was high up, near the outer side of the cecum and ascending colon. Both appendices were removed through the incisions made, but necessarily at a disadvantage. Sometimes the appendix may be removed through almost any incision; a gall bladder incision, or even a high median, and I have taken it out without difficulty through the incision made in the operation for umbilical hernia. In my judgment, if the appendix cannot readily be removed through the incision selected, it is better to make a new one rather than to enlarge the old beyond reasonable limits, or in a direction that violates unduly anatomical and mechanical principles. Accordingly then, I have, when necessary, supplemented the lateral incision by a low median and, recently finding the lateral incision inadequate, secured the desired result by an incision high up, parallel to the lower margin of the thorax.

In this patient the cecum occupied the usual location of the hepatic flexure of the colon and the appendix lay on the right kidney. This abnormality is not unique, as might perhaps be supposed, and is easily explained embryologically. It is due to the persistence of the location of the cecum normal to one period of fetal life. I had occasion at one time to open an abscess of the appendix at a point corresponding to McBurney's, but on the left side, instead of the right. I do not believe that this was a case of transposition of the viscera, but that the cecum was movable and the appendix long, allowing perforation of its tip to produce trouble in an unusual location.

In the selection of an incision, I am willing to admit that other incisions than those strictly anatomical must at times be used. No operator should, however, constantly and systematically violate anatomical principles to an extent that no technical skill can overcome. I have already given directly and by implication a proper amount of credit to the value of McBurney's incision, which, with Weir's modification, meets all ordinary requirements. Next in standing, I value the median incision, particularly in women, where there is an assurance or a chance that the pelvic viscera may require attention. The Gill Wylie incision cannot fail to appeal to the artistic sense. Its closure is practically perfect. It is not as well adapted to complicated cases as the McBurney, but certainly deserves much more recognition than it has received.

The old direct oblique incision is useful at times in operating to open an appendiceal abscess high up and to one side, and in this class of cases also it may be necessary in rare instances to enlarge a McBurney incision by cutting upward across the fibres of the internal oblique and transversalis. Probably much of the trouble from herniæ that followed the direct oblique incision rose from an improper closure. Through and through suturing, formerly much used, results in a thin weak scar where there should be a thick muscular wall of crossed fibres. Layer suturing, with special reference to the transversalis fascia, the fasciae between the muscle layers and the fascia of Scarpa, will restore the wall to something like the original appearance and strength.

The vertical incision through the outer border of the right rectus certainly has distinguished advocates, but in my opinion it should not be used in interval cases. If an abscess points at the outer border of the rectus and a vertical incision is elected, it should be made through the linea semilunaris lateral to the sheath of the rectus, thus avoiding the trap door effect produced when the cut is made into the sheath and the muscle retracted. It should never exceed an inch and a half in length.

A THEORY AS TO THE UNTOWARD EFFECTS OF DIPHTHERIA ANTITOXIN; PROPHYLAXIS IN SUSPICIOUS CASES.*

By RAYMOND WALLACE, M.Sc., M.D.,

CHATTANOOGA, TENN.

As late as 1905 Osler[1] stated that the most common untoward effects of diphtheria antitoxin "are urticaria and arthralgia, but they are trifling and unimportant." Reynold Webb Wilcox[2] asserts that "authentic cases of sudden death have never been reported and the consensus of opinion is that the treatment is harmless." Anders[3] (1907) states that "two fatal cases have been reported, one that of a healthy boy five years old, the result of an injection of Behring's fresh serum as a preventive;

*Read before the Chattanooga and Hamilton County (Tenn.) Medical Society, June, 1910.

death within five minutes; the other occurred in Berlin." Hare[4] (1907) says "the only disagreeable effects of antitoxin in large doses is the subsequent development of some pain or soreness in the joints or the appearance of a roseolous rash; but even if these symptoms appear they are not serious and need give no alarm." Welch and Schamberg[5] state that "it may be well to mention the fact that more than one death has been reported immediately following the injection of serum. This accident has been almost entirely confined to the use of the serum for immunizing purposes. While no very satisfactory explanation has been given for the occurrence of these sudden deaths, it is not believed that they were caused by the serum *per se*. The only ill effect which we are able to attribute to antitoxin with any degree of certainty is a peculiar exanthem, often attended with rise of temperature and more or less joint pains." Salinger,[6] in 1905, assures the physician that he "should not be too cautious with the dose, further that he need not fear any secondary deleterious effects * * * and in the cases mentioned in literature in which death occurred this was due to entirely different causes than use of the serum." Kerley[7] (1907) makes no mention of pronounced dyspnea or sudden death following the administration of diphtheria antitoxin. Forcheimer[8] (1906) says "it cannot be denied that sudden deaths have followed the injection of antitoxin, but they are as rare as are the deaths following the subcutaneous administration of any drug and represent a very minute chance of risk to the patient." French[9] (1907) states that "the experience of McCollum of Boston has demonstrated the entire safety of enormous doses * * * and the only untoward effects of the antitoxin treatment are a possible rise of temperature, a cutaneous eruption, and rarely the formation of an abscess at the point of injection." Gillette[10] reports thirty cases gathered from recent literature and from personal letters, of alarming dyspnea, urticaria, and collapse following the injection of serums, chiefly diphtheric, with sixteen deaths, largely within from five to fifteen minutes after the first administration. Some of the reported cases were susceptible to horse and stable odors, some were asthmatic subjects, while others, including several fatal cases, had no history of respiratory disease or distress.

Dr. Rolfe E. Hughes of Laurens, S. C., has furnished me with notes of the following unpublished case. I give his own words in a letter of February 2, 1910: "To be brief, my man, a bank cashier, twenty-nine years old, a neurotic, as the family all are, was given one-half of a 2,000 unit syringe, in other words, 1,000 units, his wife taking the other 1,000. This proves nothing wrong with the serum, as the wife had no reaction. Five minutes after taking he began to vomit, broke out in a nettle rash consisting of large confluent wheals, breathing became labored, general edema developed, and in thirty minutes he was dead. No autopsy was permitted. I was careful to inject no air; I sterilized the needle by wiping it in alcohol. I did not use heat; there was no clot. There was no paralysis and there were no signs of clot. Simply, so far as my associate and myself were able to observe, it was a case of idiosyncrasy." Dr. Hughes adds that about the same time Dr. Wurtz in Pennsylvania lost a case with circumstances very similar except that the victim had asthma.

With the rapid advance of serum therapy, and the marvelous achievements in diphtheria with antitoxin, it is peculiarly distressing to have even the shadow of a doubt thrown upon the absolute safety of serum properly administered. It is true that the exceedingly small percentage of cases resulting in death or alarming symptoms is no larger than the usual percentage with individual idiosyncrasy to many drugs, notably quinine.

The occasional disastrous effects from the use of horse serums, notably diphtheria antitoxin, demand, if possible, a classification of the individual types in which its use would probably be distinctly perilous, and a consideration of prophylaxis and treatment.

The earlier cases of death following the administration of antitoxin were generally thought to be due to a direct heart paralysis, either owing to some supposed impurity of the serum, to some unrecognized heart weakness, to injection of the serum directly into a vein, or to air embolism through a vein. But the report of cases in recent literature, notably the thirty detailed by Gillette,[10] directs attention to certain new phases of clinical manifestations which should give a clue to the avoidance of such disastrous results.

It is evident that most of the reported deaths have occurred in individuals with unstable vasomotor systems, the asthmatics, those suffering from hay fever, acute and chronic bronchitis, and the class in whom the odors of animals awaken attacks of coryza and dyspnea. In these the conclusion is probable that immunizing sera should be administered with the utmost caution. It is not infrequent to see transitory dyspnea and occasional local or universal urticaria following serum administration, particularly when given to normal individuals for the purpose of immunization.

In 1908 a young man, aged twenty-four, subject to hay fever and occasional brief asthmatic attacks during the hay fever season, and a mild form of chronic bronchitis each winter, was given 500 units of diphtheria antitoxin for the purpose of immunization. Within an hour he was plunged into an asthmatic attack with some cyanosis and a universal urticaria. In previous asthmatic attacks he had derived prompt benefit from adrenalin chloride (1-1000), and judging this to be a mild vasoparesis with edema or urticaria of the skin and bronchial mucous membrane, he was given a hypodermatic injection of 10 minims of adrenalin chloride (1-1000), with prompt amelioration of symptoms, and in three hours 10 minims more were given with complete subsidence of symptoms.

In a subsequent case of diphtheria in an adult, aged 38, of neurotic tendency and frequently subject to bronchial asthma, anticipating ill effects from the administration of the antitoxin, ten minims of adrenalin chloride were given one hour previous to the injection of 500 units of antitoxin, to insure vasomotor stability, and previous to each subsequent injection aggregating 18,000 units in all, the preliminary injection of adrenalin was given. No untoward symptoms were manifested and recovery was uninterrupted.

Another phase of the subject which should command attention is the element of danger in the indiscriminate usage of diphtheria antitoxin as a prophylactic agent. Many physicians have been accustomed to use immunizing doses at random among family members and without a certain diagnosis of diphtheria. There are here two dangers: First, the possibility of sudden death within a few minutes, or hours, because of an individual idiosyncrasy, and second, because of the dangers of serum disease

which occurs on reinjections after a ten-day period when the individual has become hypersensitive to the specific serum.

The term "serum disease" was originated in 1905 by von Pirquet and Schick, and should be understood. They describe two forms, the primary and the remote. Serum disease following the first injection usually has a prodromal stage of two to ten days, and bears no relation to the quantity of serum injected. Fever is usually constant and falls by lysis. A rash generally urticarial appears about the point of injection, and spreads over part of or the entire body, with marked pruritus. Joint pains are rather common, but seldom persist. No doubt this eruption, which at times is followed by pronounced desquamation, accounts for some of the reported or so-called cases of scarlet fever following diphtheria.

The remote form of serum disease follows reinjections, particularly when repeated after the tenth or twelfth day, and the incubation period is usually a matter of hours. In this form the symptoms are similar to the above, but more acute and associated with vomiting. A discussion of anaphylaxis is not pertinent to the subject in hand, but a differentiation must be made between cases of serum disease and the cases of respiratory embarrassment and sudden death which are here discussed.

I have seen several cases of serum disease of mild intensity which I shall briefly outline.

Case I.—January, 1909, M. F., female, aged 16, had ulcerated patches on both tonsils of grayish color, which bled on my attempting to raise border with swab. In twenty-four hours the membrane had spread to posterior pillars and there were slight patches on the posterior pharynx. The temperature was 101° to 102.2° and the pulse 90 to 104. Three thousand units of diphtheria antitoxin were given on the night of the second day. The throat cleared and the temperature was normal in three days. On the fourth day a marked urticarial rash with intense itching appeared about the point of injection, which spread over the abdomen and thorax. The temperature was 100° and the pulse 90. There was pain in the shoulders, elbows, and knees. In a few days desquamation of a coarse variety began, and at the end of a week the patient was normal. There was no respiratory embarrassment. This was a case of primary serum disease which might have been confused with a mild scarlatina.

Case II.—December, 1909, Mary D., aged 5 years, had suspicious tonsillitis for several days, which I treated by advice over the telephone at the request of the mother. Finally the latter became alarmed at the symptoms and I insisted upon seeing the child, who presented typical faucial and tonsillar diphtheria. I at once gave 3,000 units of antitoxin and the symptoms subsided in two days. On the fourth day the child had a universal urticaria starting from the focus of injection, which greatly distorted her appearance. Four hours after the sudden appearance of the urticaria I gave her seven minims of adrenalin chloride hypodermatically and in about five hours five minims more. The change was magical as the edematous condition almost disappeared, and a coarse, scaly desquamation followed.

Case III.—Sister of above child, aged 3 years, received 500 prophylactic units and developed urticaria of milder intensity and of slighter desquamation. No respiratory embarrassment occurred in any of these cases of typical primary serum disease, any of which might erroneously have been called scarlatina.

Several theories have been advanced as to the cause of sudden death following the administration of horse serums. Anderson and Rosenau attribute death in these cases to the direct effect of the serum upon the bulbar centers of respiration. Solis-Cohen considers it a possible uriticaria or edema affecting the pharyngeal and bronchial mucous membrane with mechanical blockage of the air cells.

Attacks of bronchial asthma are now promptly and quickly relieved by the hypodermatic injection of from five to fifteen minims of the 1-1,000 solution of the suprarenal gland. Urticaria, which is believed to be a vasoparesis, at times responds to the same treatment.

The theory then suggests itself that these sudden deaths may be related to adrenal insufficiency or inadequacy, and that prophylaxis and treatment should be directed along that line. It is certain that the majority of cases reported have died in spite of the treatment instituted, and based upon this theory, when asthmatic or other presumably susceptible individuals must have serum injections for diphtheria or other infectious disease, prophylactic doses of the extract of the suprarenal glands may preserve or reinforce the vasomotor equilibrium to such an extent that many sudden deaths may be avoided in this class of cases.

Its immediate and heroic use in the treatment of the alarming syndrome of edema, dyspnea, and urticaria would seem rational and worthy of the most thorough trial.

The relation of these phenomena to anaphylaxis is of the greatest interest, and without doubt the reaction of the latter occurs in individuals unusually sensitive to the foreign proteid. The manner of this sensitization in man has not yet been demonstrated. If there is reason to believe that the individual has been previously sensitized to foreign serum it might be wise to give at the first injection but a fractional dose, as suggeted by V. C. Vaughan, Jr.,[11] for "it is known that sensitized animals receiving less than a fatal dose at the second injection are then refractory to larger doses given a few hours or days later."

Conclusions.

1. Recognized authorities up to the present year have failed to emphasize the occasional danger of sudden death in sensitized individuals or those subject to bronchial asthma or to respiratory distress in other forms.

2. Individuals peculiarly susceptible to the odor of horses or stables and those subject to asthmatic attacks, hay fever and bronchitis should have horse serum administered only upon most urgent cause, and then with due prophylaxis.

3. Insufficiency or inadequacy of the suprarenal glands may account in the asthmatic type for the peculiar reaction.

4. The administration hypodermatically of aqueous extracts of the suprarenal glands previous to the use of serum in this class of cases is desirable in order to rehabilitate and control the vasomotor system, and may prove of great prophylactic value, as well as useful in the heroic treatment of the acute attacks of serum disease.

5. The desquamation following serum disease should not be confounded with scarlet fever.

THE AMERICAN GAME OF FOOTBALL: IS IT A FACTOR FOR GOOD OR FOR EVIL?

By MORRIS JOSEPH CLURMAN, A.B., M.D.,
NEW YORK.

Once again has the curtain been rung down upon a football stage, and the season of 1910, like other football seasons, with all its surprises in the shape of unexpected victories and glorious and inglorious defeats, has passed away. A great mass of the public can once more resume the even trend of its existence and settle down calmly and quietly to the everyday activities of life. For a short time, perhaps, the individual heroes of the gridiron will be thrust before an admiring host of hero-worshippers. But even this will not last long and, after a decent interval, only the archives of athletics will record the achievements of 1910 on the football field.

It cannot be taken amiss if at this stage we lend ourselves to some thoughtful considerations concerning this great American college sport. Nor will it be out of place if we attempt to analyze from a medical standpoint, and also, with due fairness and impartiality to the game, from several other standpoints, the various factors that enter into the composition of this strenuous form of collegiate and intercollegiate athletics.

It is a strange yet significant fact that of all the college sports, including baseball, track athletics, hockey, lacrosse, basket-ball, handball, cricket, rowing, tennis, golf, fencing, swimming, and wrestling, the only sport which constantly involves a positive risk to the life and health of the participants is football. Nor can the most ardent advocates of the game gainsay this, in spite of the changes instituted to create what is at present popularly designated as Reformed Football.

It has required over twenty years of evolution before radical reforms in the game were thought necessary in order to diminish the fatalities and serious accidents that every season proves to be a constant element in the game. And yet, even since 1905, when the "new football" was initiated, the close of each football season leaves behind it the usual, and now almost expected, list of lives snuffed out while yet in ruddy and vigorous health, and terrible accidents that involve maimed bodies and limbs which leave the unfortunate survivors with stigmata of ill-health and corporal delinquencies for the rest of their days. And all of this is offered up to the football Moloch, that "horrid king, besmear'd with blood."

To illustrate this more specifically let us cite some actual figures. In 1905 Dr. Robert E. Coughlin records (Medical Record, June 2, 1906) that 26 deaths were directly due to football. In 1906 the *Chicago Tribune* records that football was the cause of 11 deaths and 103 cases of serious injury. In 1907 there were again 11 deaths and 97 cases of serious injury.

An analysis of the marked diversity of the direct causes of death brought on by football in the 26 cases of 1905, as given by Dr. Coughlin, are as follows:

Abdominal injuries	7
Dislocation of spine with paralysis	3
Concussion of brain	5
Fracture of skull	5
Cerebral hemorrhage	2
Fracture of rib (the same being driven through the heart)	2
Fracture of spine	1
Acute peritonitis	1

No elaborate comment is required upon a sport that permits of the possibility of a player's rib being broken and forced through the heart.

Through the courtesy of the statistical bureau of the *New York American* I am enabled to quote the appalling figures of the past three football seasons, including 1910. In 1908 there were 13 deaths and 84 seriously injured. In 1909 there were 33 deaths and 216 injuries, of which 73 were serious. In the present season of 1910 there were 19 deaths and 400 injuries, including those of a serious nature and otherwise.

Recapitulating in table form we have as follows:

	Deaths	Injuries	
1905	26	?	
1906	11	103	serious
1907	11	97	"
1908	13	84	"
1909	33	73	"
(Out of a total of 216 recorded.)			
1910	19	400	"
Total	113	900	"

What possible arguments could be advanced in favor of football to offset these gruesome figures? According to all our statistics it is safe to say that at the close of the next football season we shall again have about 20 deaths and nearly 150 reported injuries of a serious nature. To all serious minded people it should be a frightful thought that the finger of Fate to-day marks out these unknown 20 of the pick of our young men as a sacrifice upon the altar of the 1911 football season!

In this connection it is of interest to know what President Eliot of Harvard had to say of the game. He has declared that football "causes an unreasonable number of serious injuries and deaths. Not one in five of the men that play football several seasons escapes without injury properly called serious, and of the twenty to thirty picked players who play hard throughout a season hardly a man escapes serious injury."

It is indeed true that "great bodies move slowly" and the public attitude toward football lends force to that adage. But the time cannot be far distant when an enlightened public will come to realize that the game of football is one of the few remaining survivals of barbarism among a civilized people and that it, too, should be discarded.

Dr. Eliot says (*Boston Medical and Surgical Journal*, April 1, 1909): "Although the game of football has been made more open and interesting by the new rules and some of the foul play has been prevented by the neutral strip and other devices, the game still remains unfit for college uses and affords a demoralizing spectacle for the immense crowds which gather to witness the chief games. It is reasonable to expect that the barbarous stage of public opinion and college opinion

concerning athletics, which in this country has been partly the result of inexperience in competitive sports and partly of the general predisposition to exaggeration in pleasures which characterizes Americans, will pass away before many years."

The advocates of football will argue that football, as reformed to-day, has done away with most of the dangers attached to it. But they cannot claim that it has as yet eliminated all the possibilities of danger to the contestants. The daily press throughout the country attests eloquently to the number of victims that each football season claims, both as to loss of life and serious bodily injury.

As long as the rules of the game will permit of a line of strong and hardy athletes rushing upon another line of similarly endowed athletes so as to gain the precious "yards," so long will danger lurk in the game. As long as it is permitted to tackle a player who is running at full speed and high momentum with the football tightly held to his chest and who, therefore, cannot adequately protect himself from a sudden and violent impact upon the ground, so long will football continue to be a dangerous and serious menace to the contestants. And as long as the exigencies of the game permit of one man being overwhelmed by a mass of players falling upon him in the attempt to get the referee's official "down," so long must danger to life and limb necessarily and inevitably be present.

If football could be reformed so that the above essentials of the game were eradicated, then football would no longer be football and the immense magnetic attractive power it now has for a great public would perhaps be lacking. If a completely reformed football game could totally eradicate the elements of tackling, mass plays, rugged and strenuous "interference" and men being covered by masses of athletes piling on top of them, then what would be left? Perhaps a modified and hybrid form of basket-ball. And yet, basket-ball, in spite of its numerous advantages, has not and will never have the hosts of enthusiasts that football claims.

Indeed, he who has not seen a football crowd at a great college football game has missed seeing his fellow-creatures in as near an approach as possible to an elemental type of civilization. Staid and dignified men who are noted for sobriety are converted into howling dervishes. Tender-hearted women, during an exciting stage of the contest, shriek themselves into a condition of frenzy and real hysteria. The dignified judge will pay scant attention to the fact that his high hat has been crushed over his ears and irrevocably ruined by the fist of a frenzied freshman sitting behind him; and the poise of a lady's hat, which has been shamefully twisted half a circumference, will be the last thing in her thoughts while the excitement of the game runs high.

But, after all, is not the attraction for football exactly the same as that which the ancients had for gladiatorial contests and which the Spaniards have for bull-fights? Is not that attraction identical with the drawing force of the medieval tournaments and jousts and with the present-day prize fights of noted heavyweights? Indeed, a spectator once naïvely defined a football game as a prize fight multiplied by eleven.

Coming down to a final analysis we can only attribute the wonderful popularity of football to primitive causes. It is the innate love that is present in the race to experience, even though it be as spectators, the fierce pleasure of the rough encounter of two powerful enemies or the physical struggle of opponents to conquer each other. Perhaps, also, there is a secret, but deep-seated and primitive, element of cruelty in us that is only satisfied by the exhibition of rough and brutal force between two opponents.

If the only argument that could be advanced against football were that each year several players will be killed and several others seriously injured, then that argument would be sufficiently potent a cause for the abolishment of football. Nor is that argument at all fanciful and improbable. While complete statistics are difficult to obtain, still there is not a single season within the memory of the writer, including the present season, that some players have not been killed and many others so seriously injured as to leave behind a weakened and irretrievably damaged constitution. Is the sport so valuable and necessary that we can afford to pay this priceless yearly toll?

Nor can it be claimed that serious accidents do not happen with well-trained teams. Such an assertion is disproved by facts. The writer calls to mind the lamentable death of a West Point cadet last year during one of the regular football contests. And surely West Point trains its men thoroughly. Even if fatalities and injuries were only to occur with poorly trained teams, still each season is bound to have many such poorly trained teams among the smaller and lesser known schools so that a vicious circle of disasters cannot be eliminated from this sport.

There is another element in the game of football upon which the medical man is peculiarly competent to act as a final authority, and that is the element of fatigue and exhaustion. Physiology teaches us that any activity which involves long continued and very violent exercise cannot result beneficially to the human system. And football is essentially a game that demands just such violent and exhausting strains and drains from the participants of the game. Even from a layman's point of view it would not need any great stretch of the imagination to see that any physical exercise that leaves a man tottering, weak, and in a fainting condition can only be of dubious value from an athletic standpoint.

Professor James of Illinois has stated that "nearly all football players have weak hearts and are more liable to diseases of other forms than men who exercise moderately." Indeed the "irritable" heart has for undoubted etiological factors long continued and violent physical exertion. While statistics of the after life of football men are difficult to obtain, still we know that severe and violent physical stress extending over a period of time of eight weeks or more may cause ultimate myocardial degeneration and eventually bring on aortic valvular disease.

During the period of two months that the football men are engaged in their training and playing, it is only physiologically natural that their hearts and their muscles should be undergoing a compensatory hypertrophy to enable them to accomplish the increased and unusual work that they are called upon to do. But after the season is over and the "break" in training takes place, those who have not been injured will still have to "pay the piper for their dancing." Their hypertrophic hearts and muscles when no longer called upon to bear the arduous exertions to which they have been de-

veloped must necessarily undergo, to some extent at least, atrophy from disuse, and often enough such changes in muscular structure from a normal to a hypertrophic condition and then back again to atrophic changes are accompanied by muscular and myocardial fatty degeneration. In a measure this same argument might be advanced against several other sports and justly so, perhaps, but there is little question but that it applies preeminently to football.

If it were left to the physician to advise the best sort of exercise, he would recommend games which do not tax the individual to the utmost point of endurance and in which many could participate and take an active part instead of a mere handful of specially picked and over-trained men as is the case with football. It is not the strenuous and exhaustive exercise kept up for a comparatively brief period that is of value, but the daily graded and moderate exercises kept up for years that develop a man to the highest grade of physical efficiency. Naturally enough a regular life with clean habits of existence are necessary adjuncts to such a development.

After all we must wonder at a university or college specializing itself so intently upon the training of a small squad of men who are chosen to uphold its athletic prowess upon the gridiron, while at the same time practically neglecting the physical education of the remaining larger mass of students. Indeed, it is an interesting fact that out of a university with 3,000 students at the utmost only fifty are actively occupied in the game of football. The remaining 2,950 only strain their lungs at spasmodic intervals in cheering and encouraging the fifty players. Would not much more of lasting benefit be accomplished if the same amount of energy were expended by the colleges to institute a system whereby *all* the students could be educated physically as well as mentally?

Some of our larger universities are already leading the way in this direction as, for example, Cornell, which is laying out an extensive athletic field that can be used by all its students for athletic sports and diversions. Columbia, most notably of all our American universities, has recognized the evils of football and has not hesitated to abolish it from its college activities. Indeed, Dr. Nicholas Murray Butler, its learned president, while believing firmly in the advantages resulting from athletics and health-giving physical exercise for the entire mass of students, has been most firm in his stand against football.

By a peculiar combination of sheer good fortune and luck no fatality has occurred of late years in the annual football games of such colleges as Yale and Harvard. But what if the benign smile of Dame Fortune in dealing with these great universities should without warning be converted into an ugly and malignant frown? Let us assume for a moment the perfectly plausible and possible supposition that at the next contest between these two great American universities one or two players will be so seriously injured as to cause death. In such an event there is scarcely the shadow of a doubt that football would then be abolished by Yale and Harvard. With three of our leading universities showing the way it would not be long before public opinion would give the final death blow to a sport that should long ago have been thrown into the discard-heap. Why wait until such a fatality occurs in a Yale-Harvard game? The most humane and wisest policy would be to anticipate such a disaster and thus preclude the possibility of its arising.

There is still another phase of football that should not be slurred over. Just as it is a medical fact that a meal is better digested and assimilated when it is eaten with good appetite and zest, so by analogy and also by fact does it hold equally true that it is only that sport which is accompanied with fun, enjoyment, and love of the sport itself, which will do the most good in building up and developing the body physically. But very few football players will assert truthfully that they enjoy the hard grind of the daily practice preceding the games. The element of fun is absolutely lacking in the wearing and tearing routine of the work preliminary to the "big games." Indeed, in a large measure, it is only the sustaining knowledge that they are going to play in the open field before an enthusiastic multitude which will applaud and cheer their efforts that spurs the players on in the grind of daily practice.

There are still other elements in the game of football that for discussion come more naturally within the scope of men who are authorities on academic questions, of men whose domain is psychology, of men who are conversant in matters of pure ethics, and of sociologists.

Such for example are (1) the disadvantages in scholarship that the players suffer who devote so much of their energies and time to football; (2) the psychological aspects of an enthusiasm among spectators of a football game that is so extraordinary as to be not far removed from a true form of hysteria; (3) the great temptations that arise in the course of the game for the use of unnecessary roughness and the employment of surreptitious and easily overlooked foul play; (4) the exaggerated ideas of importance that college players, who should be students first, last, and all the time, unconsciously assume when they are so publicly praised for their work on the gridiron; (5) the false valuation of college standards that prospective students and others get from football reports of the daily press.

Before closing this discussion it might be well to reiterate once more the attitude of medical men toward college sports and athletics in general. (1) The primary aim of all interscholastic and college sports should be the improvement and symmetrical development of the body so as to leave it stronger and more competent to combat the inroads of disease and to engage in the daily activities of life. (2) No form of athletics should be so strenuous and fatiguing as to leave the mental faculties inert and too tired to accomplish and to assimilate the required amount of scholastic work. (3) College athletics should be so reformed that *all* the students would be able to derive physical benefits rather than the comparatively few that make the college teams. (4) Any form of athletics that constantly involves the element of death and serious injury should be abolished.

In composing this paper the writer, who is a true lover of athletics and outdoor sports, has not been actuated by motives of prejudice or narrowmindedness toward football. He has dealt with the subject from the genuine and earnest standpoint that the family tree of collegiate athletics can be improved and made more useful by the justifiable lopping off of one distorted and unhealthy branch—the branch of football.

THE MUTATION THEORY AND DISEASE.

THE name of the Dutch botanist, Hugo de Vries, is now closely linked with the theory that species are not produced by slow transformations, the indefinite or fluctuating variations of the Darwinian theory, but are the result of sudden changes, or sports, which are fixed by heredity. The doctrine of heterogenesis had already been enunciated as early as 1864 by the German physiologist Kölliker, as a factor in the evolution of species, and even Darwin himself had recognized that natural selection improves but cannot create anything new. Long before the appearance in 1901 of de Vries' work, *Die Mutationstheorie*, William Bateson of England had emphasized the evolutionary importance of discontinuous variations. It is now generally accepted by biologists that the theories of natural selection and of mutation are not incompatible; that variations in nature may arise spontaneously, and if fit, may persist as new species, to be perpetuated by heredity; and furthermore that such sudden variations may be improved by natural selection.

Within recent years, in the philosophic interpretation of the phenomena of disease, there has crystallized a tendency to apply more fully than heretofore the fundamental laws of biology. This tendency began with the acceptance of Virchow's doctrine of cellular pathology, and continued with the recognition, as important factors in the natural history of disease, of selection, adaptation, degeneration, regeneration, and Mendelian heredity. The theory of mutation is the latest addition to this list.

In 1908, E. Rabaut explained with apparent success the origin of human teratological structures on the basis of the mutation theory. Thus monstrosities, polydactylism, polymastia, etc., are regarded by this author as sudden variations rather than the result of intrauterine traumatism or arrest of development. The application of the mutation theory is further exemplified in the case reported by Réaumur, of the hereditary transmission of polydactylism through several generations. Of similar significance is the case reported by H. P. Newsholme in *The Lancet*, December 10, 1910, of the inheritance of webbed toes by twenty-two members in a family of twenty-nine, during three generations.

An elaborate application of the mutation theory to pathology in general, and to cancer in particular, is attempted by M. Jankelvitch, in the *Revue de Médecine*, December 10, 1910.

Basing his generalizations upon the recognition of teratological manifestations as mutations, he conceives that analogous local aberrations, invisible or purely functional, may profoundly modify the activity of an organ and by virtue of the principle of correlaton may disturb the physiological equilibrium of the entire body. The morbid predisposition is the result of certain microscopic or ultramicroscopic changes of a sudden character arising during embryonic life.

According to this author cancer cells are formed in the course of embryonic development, as the result of mutations or variations. When this development is complete the aberrant cells not only are of no value to the organism but may even be harmful. At the same time they retain their native property of unlimited proliferation, which persists in a latent state, awaiting only a favorable movement before manifesting itself. The health of the entire organism depends upon the mutual interdependence of its constituent parts, which are subordinated to the needs of the body. This subjection of the different groups of cells, tissues, and organs is effected only at the expense of a continual struggle, which is marked by periods of broken equilibrium. The regulating power of the organism is, however, capable of reestablishing this equilibrium.

In this manner is explained the fact that the power of riotous multiplication inherent in the cancer cells is held in leash. But if for any reason the regulating mechanism of the body should fail, the cancer cells secure their liberty and proliferate without regard to the needs or safety of the entire organism. What are the causes of this loss or weakening of the regulating power of the body? One of these is advancing age, with its associated diminution of vitality. This is all that Jankelvitch suggests among the various factors recognized in the etiology of cancer, in bringing his hypothesis into harmony with known facts.

In this ingenious theory one readily perceives the familiar features of that already advanced by Ribbert, who recognized in the genesis of cancer the loss of the power by means of which the proliferative activity of the cells is kept in restraint. The former hypothesis, which we have just given in outline, goes further, however, in that it seeks to explain the origin of the cancer cell on the basis of the mutation theory.

If mutations play an important rôle in biology, there can be little doubt that they share in the evolution of disease. Is it possible that in this theory may be found the key to many an unsolved problem in pathology? There is an almost unlimited field for speculation in the thought that the starting point in many diseases, such as those of metabolism, is an accidental variation or sport, analogous to those familiar to the botanist and animal breeder. This variation may be functional as well as organic.

PROPHYLAXIS OF VENEREAL DISEASES IN THE UNITED STATES ARMY.

Some few months ago Colonel L. M. Maus, Medical Corps, U. S. A., published an article on "Venereal Diseases in the United States Army, Their Prevention, and Treatment," in the official journal of the association. In the December issue of the *Military Surgeon* he makes further observations on the same subject. In 1905 Lieutenant Colonel H. I. Raymond of the Army Medical Corps took up the method of treating venereal disease in the German army by calomel ointment in connection with the organic silver salts. Raymond furnished each soldier in the Columbus Barracks, Ohio, with what was termed the "K" packet. This packet contained a small box of blue ointment, a vial containing 2 c.c. of a 5 per cent. solution of a colloidal silver preparation, and a medicine dropper. So far as the method of treatment was concerned it was satisfactory, but the results were unsatisfactory, for the reason that the men would not use them generally. In fact, for various reasons, these packets were unpopular. Recently several modifications have been made in regard to both the preparation and employment of these protective methods. Tubes of different kinds have been devised which, though taking less room than the "K" package, have been yet found too complicated and cumbersome. Maus finally evolved a formula consisting simply of calomel, 25 per cent., and common lard, 75 per cent., which, if properly used, has been found to be an almost absolute preventive of syphilis, gonorrhea, and chancroids. Maus recommends that the War Department issue an order to the following effect: 1. That monthly lectures on general military and personal hygiene be required of medical officers to commands not only for the purpose of educating the officers and men in the subjects, but to enable them to preserve their health against contagious and other preventable diseases. 2. That weekly physical inspections of companies or detachments be made by a non-commissioned officer, under the direction of the company commander, the men being in undershirts, drawers, and bare feet, immediately after the Saturday morning inspection for the detection of personal uncleanliness, physical defects, condition of the teeth and feet, and contagious diseases. All men suffering from physical disqualifications or disease should be ordered at once to the hospital for the action of the surgeons. 3. That three antiseptic tubes be made a part of the kit for the soldier and the men instructed in their use, with such orders as may be necessary. 4. That soldiers suffering from contagious diseases rendered preventable by the use of the antiseptic measures prescribed be regarded as having disobeyed a sanitary order and held guilty of violation of the sixty-second article of war.

The above proposed regulations are certainly sufficiently drastic and will probably meet with little favor among the rank and file of the army. On the other hand, the ignorance of the private soldier with regard to the danger of contracting venereal diseases is colossal and it is a question whether he should not be forcibly protected against the results of his indiscretion and carelessness. The fact is obvious that venereal diseases are far too prevalent in all armies and that widespread preventive measures must be undertaken.

Public Health in Pittsburg.

For some considerable period of time there has been much dissatisfaction among the more patriotic citizens of Pittsburg with regard to the manner in which the sanitary affairs of the city were managed. Improvements have been introduced, but still the situation, so far as public health is concerned, cannot be termed satisfactory. In the *Survey* of December 17 is an article on the "Pittsburg Health Situation," by Samuel Hopkins Adams, who takes a retrospective and present-day view of health matters in that city. He points out that in May, 1909, Pittsburg formed an autonomous Department of Health, but deplores the fact that the original executive of the health bureau was displaced in favor of another and less fitting man later on. However, it must in fairness be stated that the death rate of Pittsburg has greatly decreased and now stands at a low figure. Infectious diseases have decreased and typhoid fever, which was once a foul blot on the reputation of the city, has been practically conquered. Infant mortality, a fairly good criterion of the state of public health generally, has diminished, chiefly, according to Mr. Adams, in consequence of the supervision of the milk supply, of the greater care of sick babies, and of the instruction given to visiting mothers by visiting nurses. Tuberculosis is stated to be rampant in Pittsburg and it is claimed that adequate steps have not been taken to stay its ravages. In short, Adams contends that, while improvement in public health matters has taken place in Pittsburg, improvement has been delayed and even retrogressions have occurred because politics are too evident in the Health Department. On the whole, however, and despite Mr. Adams' pessimistic view, there are evident signs that the great steel city is at least awakening from its lethargy, if not yet fully aroused. Surely no city has had more politics or more politicians in its Health Department than New York had not so many years ago; yet there were good men in the department, men who proved themselves to be such capable sanitarians that even the politicians feared to anger the community by displacing them; and so the leaven of their presence worked to bring the department to its present high level. And so we are sure will the public opinion of Pittsburg demand the retention of the honest and the capable subordinates in the department who have already accomplished much and have given promise of greater improvement in the future.

The Decline of the Birth Rate.

It is well known that in all civilized countries the birth rate has declined and is declining, but the reasons advanced for this vary considerably. Professor Brentano in the *Economic Journal* for October sets forth his views on the subject. He premises that the more prosperous the country or district the less fertile the inhabitants. For example, France, the richest country of the world, has by far the lowest birth rate. Native-born Americans again have few children, indeed it has been computed that if the continued emigration from Europe were to cease this part of the continent would, in view of the fertility of the negro, become black in quite

a short predeterminable time. In Australia, where the working classes are better off than anywhere else in the world, the decline of fertility has been almost the greatest of all. Professor Brentano rules out altogether any connection between the decline in the birth rate and religion or race. It first appeared in France when that land was predominantly Catholic, and it is claimed that only poor Catholics and poor Jews yield a high birth rate. Moreover, it cannot be attributed to increased industrialism or to the growing tendency to live in towns. The French peasants have fewer children than the urban laborers. The professor thus specifies the reasons why fertility should decrease with increased prosperity: 1. The diseases of sex which appear as concomitants to postponed marriages. 2. Mental disease caused by nervous strain. 3. Diminution of desire for offspring, both because of competing pleasures and because of a more refined feeling for children. The most potent check, however, is the cost of maintaining a larger number of children, and the decline of infant mortality is another cause. Attention is also drawn to the fact that, although the birth rate has declined, the surplus of births over deaths has never been so great. Professor Brentano appears to have succeeded in the object which inspired his article, that of attempting to shatter the Malthusian creed. The most hopeful feature of the present discussions concerning the decline of the birth rate in civilized lands is that the master minds of medical science are grappling with the problem of how to improve the race physically and mentally.

News of the Week.

City Death Rate.—For the week ending December 24 the number of deaths was slightly larger than for the corresponding week of last year, the increase being chiefly in the deaths among aged persons. In 1909 there were 1,562 deaths, the death rate being 17.85 per 1,000 of population, while in the same period of 1910 there were 1,690 deaths, a rate of 18.36. Among children under five years of age there were 385 deaths, a decrease of 52. Pneumonia caused 334 deaths, an increase of 31; pulmonary tuberculosis 107 deaths, an increase of 8, and heart disease 231, an increase of 10. Twelve deaths were due to typhoid fever, an increase of 50 per cent.

Density of Population.—According to the figures of the Census Bureau, Rhode Island leads the States as regards density of population, having 508.5 persons to the square mile. Massachusetts is second with 418.8; New Jersey third with 337.7; Connecticut fourth with 231.3, and New York fifth with 191.2. The other States having more than 100 to the square mile are Pennsylvania, 171; Maryland, 130; Ohio, 117; Delaware, 103, and Illinois, 100.7. At the other end of the list is Nevada with only seven-tenths of a person to the square mile. Wyoming has 1.5 persons, and Arizona 1.8. Eight other States show an average of less than ten persons to the mile.

Michigan Tuberculosis Association.—The Board of Directors of the Michigan State Association for the Prevention of Tuberculosis held a meeting at Ann Arbor on December 9, Dr. V. C. Vaughan presiding. The resignation of Dr. Warthin as secretary of the association was accepted with regret. The Board decided to ask the Legislature for a grant of $1,000 a year for the next two years, and to work during the coming year for the establishment of a State Museum of Preventive Medicine. The *Journal of the Outdoor Life* was adopted as the official organ of the association.

Hospital Site Enlarged.—The Presbyterian Hospital, New York, which already holds one entire block on the east side of the city as a site for its proposed new buildings, on December 27 acquired another plot consisting of twelve and a half city lots in the block directly to the west. The trustees of the hospital have had this property under option for some time, intending, it is said, to erect a nurses' home thereon. It is probable, however, that following the recently announced alliance with the College of Physicians and Surgeons these plans may be somewhat changed.

State Dental Service.—By the appointment of Dr. H. L. Wheeler and Dr. W. A. White as dental consultants and special lecturers on oral hygiene of the New York State Department of Health, Commissioner Porter has the distinction of being the first State Commissioner in the United States to enlist the assistance of members of the dental profession on behalf of the health of the community. The duties assigned to them comprise the giving of public lectures on the subject of mouth hygiene and the prevention of tooth decay, consulting with local health boards and school authorities with regard to the inspection of the teeth of school children and the opening of free dental clinics.

The "Journal of Biological Chemistry."—The death of Dr. Christian A. Herter, editor-in-chief, has caused some inquiries in regard to the future of the *Journal of Biological Chemistry*, and the remaining editors have therefore issued a statement assuring the medical public of its continuance. At the time of the inception of the *Journal* Dr. Herter invited four others to join with him in forming a corporation having for its object the issuance of the paper, and this corporation will now assume full charge of and continue the publication without interruption. As heretofore the office of the *Journal* will be at 819 Madison avenue, New York.

New Hospital.—Under the auspices of the Miriam Barnet Dispensary Association, a new hospital, having provision for the care of forty patients, will shortly be opened in Paterson, N. J. The association has leased the Crosby mansion in the center of the city, and plans for converting it into a hospital are now being drawn.

Proctological Society Prize.—The American Proctological Society announces a prize of $100 to be awarded to the author submitting the best original essay, having for its subject any disease of the colon. Essays in competition must be submitted to the secretary of the committee, Dr. Lewis H. Adler, Jr., 1610 Arch street, Philadelphia, on or before May 10, 1911. Each essay must be typewritten, marked with a device or motto, and accompanied by a sealed envelope having on the outside the same device or motto, and inside the name of the author. The competition is open to graduates of medicine (not fellows of the society) and to members of the senior classes of all colleges in the United States or Canada. Further particulars may be obtained from the secretary of the committee.

Marriages in New York City.—Marriage licenses to the number of 51,537 were issued by the Marriage License Bureau in New York during 1910, an increase of 5,141 over the previous year.

A Member of the County Medical Society Expelled.—By a vote of 392 to 38 the New York County Medical Society at a meeting on December 27, expelled Dr. Robert Kunitzer, chief of the Sydenham Hospital, from membership in the society. This action, the first under the circumstances in the history of the society, was taken after Dr. Kunitzer had been allowed to make a personal defence to the charges brought against him by the Board of Censors, on which he had already been found guilty by the Comitia Minora. The main charge against Dr. Kunitzer was that he had falsified the records of the hospital in regard to certain operations alleged to have been performed by Dr. L. A. Ewald. The investigation of the records of Dr. Ewald's cases was begun soon after the publication of the German Hospital Festschrift, two years ago, and as a result Dr. Ewald was, last June, suspended from membership in the society for one year. At a meeting of the Board of Censors held on December 12, however, it was voted to reinstate him, in order that the matter might be passed upon by the society as a whole. Upon receiving notice of his reinstatement Dr. Ewald immediately sent in his resignation, and although this has not been accepted, he has obtained a temporary injunction from a Supreme Court Justice, restraining the society from acting upon or even discussing the matter of his expulsion, on the ground that he is not a member of the society. Dr. Kunitzer has also threatened to carry his case before the law courts.

Seizure of Eggs.—Nine tons of rotten eggs were seized by a United States Marshal at a refrigerating plant in Jersey City, N. J., recently. This is one of the largest seizures so far made by the Government in its crusade against the sale of bad eggs to bakers, confectioners, and others. The Jersey City Board of Health will destroy the eggs.

Automobile Troubles.—An investigation of the use of the automobiles owned by the New York City Department of Health is now promised by the Commissioner of Accounts. It is said that one car belonging to the city has actually been let out for public hire, but this is blamed to the chauffeur in charge of it. Other charges concern the purchase of a car for the use of one of the officials. An old car which had been used by him while acting as street commissioner was given in partial payment, and the same car was subsequently repurchased by the Street Cleaning Department. The official contends that the Aldermen in granting him an appropriation for a new car gave him also the right to include the old car in the purchase price, but the Comptroller has refused to pay the bill on the ground that city-owned property cannot be disposed of except at public auction.

Herter Foundation Lectures.—The Faculty of the University and Bellevue Hospital Medical College of New York announces that Prof. A. R. Cushny of the University of London will deliver the annual course of six lectures, under the Herter Foundation, for 1911. The lectures will be delivered every afternoon of the week beginning January 9, at 4 o'clock, at the Carnegie Laboratory, 338 E. Twenty-sixth street. The subject of the lectures will be "Irregularities of the Heart."

Cost of Tuberculosis Fight.—The National Association for the Study and Prevention of Tuberculosis reports that during the year 1910 nearly $15,000,000 was spent throughout the United States in the fight against tuberculosis. This amount is nearly double that used during 1909 for the same purpose. Of it, over eleven million of dollars was used for treatment in sanatoria and hospital. Nearly one-third of the total amount is credited to New York State.

Dies at 104.—Frank King, a resident of Grafton, N. Y., died at his home on December 29, aged 104 years. He was the father of thirty-six children and left twenty-six grandchildren and the same number of great-grandchildren.

New York City Statistics.—The year 1910 has shown the lowest death rate in the history of the city and the highest birth rate. The total number of deaths was 76,743, the rate being 15.98 per 1,000 of population. Among infants the mortality rate was 119 per 1,000 of reported births. The total number of births recorded was 129,080, an increase of 6,105 over the total for 1909.

Cuban Medical Affairs.—From Cuba comes the news of the death on September 4 of Dr. J. N. Dávalos, chief bacteriologist to the National Laboratory, and on September 7, of Dr. J. L. Duenas, a member of the staff of the Crónica Médico-Quirúrgica, and a delegate to the Third International Congress of School Hygienics in Paris.

A national association of ophthalmology and otolaryngology has been organized in Havana, with a membership of about forty of the men in Cuba, who are interested in the subject. Dr. J. Santos Fernandez has been elected president; Dr. Emilio Martinez, vice-president, and Dr. F. M. Fernandez, secretary.

Charitable Bequests.—By the will of the late Craig D. Ritchie of Philadelphia the sum of $30,000 is bequeathed to the Presbyterian Hospital for the endowment of four free beds. The University of Pennsylvania also receives a trust fund of $50,000.

East Side Physicians' Association of New York.—At a regular meeting of the association held at the Café Boulevard on December 22, the following officers were elected for the year 1911: *President*, Dr. I. Seth Hirsch; *First Vice-President*, Dr. Sigmund Epstein; *Second Vice-President*, Dr. Charles Herrman; *Secretary*, Dr. Harry G. Watson; *Treasurer*, Dr. Herman C. Frauenthal.

Wilson County (N. C.) Medical Society.—At the annual meeting held on December 8 the following officers were elected: *President*, Dr. K. C. Moore; *Vice-President*, Dr. Saliba; *Secretary and Treasurer*, Dr. E. T. Dickenson.

Cincinnati Society for Medical Research.—At a meeting of the society held in the laboratory of the City Hospital on December 1 the following officers were elected: *President*, Dr. William Wherry; *Vice-President*, Dr. S. P. Kramer; *Secretary and Treasurer*, Dr. J. L. Tuechter; *Executive Committee*, Dr. P. G. Woolley and Dr. Fisher.

Butler County (Ohio) Medical Society.—The following officers were elected at the annual meeting held in Middletown on December 7: *President*, Dr. Mark Millikin; *Vice-Presidents*, Dr. Gever, Dr. Carney, and Dr. Hancock; *Secretary*, Dr. P. M. Sater; *Treasurer*, Dr. Frank Litton.

Huron County (Ohio) Medical Society.—At the annual meeting in Norwalk on December 8 the following officers were elected: *President*, Dr. E. R. Kreider, Monroeville; *Vice-President*, Dr. F. E. Weeks, Clarksfield; *Secretary*, Dr. W. E. Gill, Norwalk.

Lake County (Ohio) Medical Society.—At the seventy-third regular meeting held on December 5 the following officers were elected: *President*, Dr. C. F. House, Painesville, O.; *Vice-President*, Dr.

J. N. Black, Perry, O.; *Secretary,* Dr. H. L. Spence, Painesville, O.; *Treasurer,* Dr. C. M. Hawley, Painesville, O.; *Delegate,* Dr. A. P. Brady, Painesville, O.; *Member Auxiliary Committee,* Dr. T. M. Moore, Willoughby, O.; *Censor,* Dr. H. W. Granel, Painesville, O.

Tulsa County (Okla.) Medical Association.—At the annual meeting on December 7 the following officers were elected: *President,* Dr. Ross Grosshart; *Vice-President,* Dr. P. R. Brown; *Secretary,* Dr. Walter E. Wright; *Treasurer,* Dr. S. D. Hawley.

Greenville County (S. C.) Medical Society.—At the annual meeting held on December 5 the following officers were elected: *President,* Dr. A. White, Mauldin; *Vice-President,* Dr. W. B. Sparkman, Greenville; *Secretary,* Dr. C. O. Bates, Greenville; *Treasurer,* Dr. R. W. Bruce, Greenville.

Mitchell District (S. D.) Medical Society.—The following officers were elected at the annual meeting on December 5: *President,* Dr. E. W. Jones, Mt. Vernon; *Vice-President,* Dr. E. F. Reamer, Mitchell; *Secretary,* Dr. W. R. Ball, Mitchell; *Treasurer,* Dr. B. A. Bobb, Mitchell; *Censor,* Dr. J. M. Howard.

Tarrant County (Tex.) Medical Society.—The following officers were elected at the annual meeting on December 6: *President,* Dr. M. Lyle Talbot; *Vice-President,* Dr. Wilmer Allison; *Secretary,* Dr. Frank G. Sanders; *Treasurer,* Dr. W. R. Thompson; *Delegate to State Association,* Dr. W. G. Cook.

Waukesha County (Wis.) Medical Society.—At the annual meeting on December 4 the following officers were elected: *President,* Dr. J. H. Voje; *Vice-President,* Dr. Noble, Waukesha; *Secretary and Treasurer,* Dr. Davies, Waukesha; *Censor,* Dr. H. A. Peters, Oconomowoc. Dr. M. R. Wilkinson was elected delegate to the State convention.

The Southern Homeopathic Medical Association held its annual meeting at Jacksonville, Fla., on December 7 and 8. The following officers were elected for the ensuing year: *President,* Dr. J. T. Crebbin of New Orleans; *Vice-President,* Dr. Robert A. Hix of Fort Smith, Ark.; *Second Vice-President,* Dr. F. A. Reed of Eustis, Fla.; *Secretary,* Dr. Lee Norman of Louisville, Ky.; *Treasurer,* Dr. H. W. Johnson of Knoxville, Tenn.

Obituary Notes.—Dr. William S. Janney of Philadelphia, Pa., a graduate of the Pennsylvania Medical College in 1854, surgeon in the United States Army during the Civil War, for twenty years attending surgeon to the Girard College Hospital, and for sixteen years surgeon to the Philadelphia Hospital, and a member of the Pennsylvania State and Philadelphia County Medical societies, died at his home of heart disease on December 24, aged 77 years.

Dr. Willis Goss Macdonald of Albany, N. Y., a graduate of the Albany Medical College in 1887, surgeon to the Albany Hospital and consulting surgeon to the Westfield Hospital; professor of abdominal and clinical surgery in the Albany Medical College, a member of the American Medical and American Surgical associations, and the New York State and Albany County Medical societies, president of the Board of Trustees of the New York State Hospital for the Treatment of Incipient Tuberculosis at Ray Brook, and surgeon of United States Volunteers with the rank of Major during the Spanish-American War, died at his home of pneumonia after five days' illness, on December 30, aged 47 years.

Dr. Cornelius Cole Bradley of New York, a graduate of the College of Physicians and Surgeons, New York, in 1885, ophthalmological surgeon to the New York Catholic Protectory, St. Joseph's Asylum, and St. Joseph's Institute, and consulting ophthalmologist to the Home for Incurables, and a member of the American Medical Association, the New York Academy of Medicine, the New York State and County Medical societies, and the Greater NewYork Medical Association, died at his home in New Rochelle of septic endocarditis on December 30, aged 48 years.

Dr. Albert Seessel of New York, a graduate of the University of Leipzig, Germany, in 1876, died at the German Hospital on December 24 after a brief illness, aged 60 years.

Dr. Ludwig Weihlan of Scranton, Pa., a graduate of the University of Wurzburg, Germany, in 1874, a member of the American Medical Association and of the Pennsylvania State and Lackawanna County Medical societies, died at his home on December 26, aged 59 years.

Dr. J. W. F. Parker, the oldest physician of Somerset, Ky., a graduate of the Medical Department of the University of Louisville in 1850, and a member of the Kentucky State and Pulaski County Medical societies, died at his home after a few weeks' illness on December 19.

Dr. Roscoe H. Goodrich of Chamberlain, S. D., a graduate of the University of Vermont College of Medicine, Burlington, and a member of the American Medical Association and of the South Dakota State and Brule County Medical societies, died at his home on December 19 after a brief illness.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

KING EDWARD'S HOSPITAL FUND, DISTRIBUTION AND EXECUTIVE COMMITTEES, HOSPITALS AND SCHOOLS QUESTION, OUT-PATIENT QUESTION — WORKING CLASS COMPLAINTS OF HOSPITALS—NAVAL REPORT—TYPHOID CARRIERS—TUBERCULOSIS, LEITH M. O. H. ON SULPHUR—TO DESTROY TSETSE FLIES—OBITUARY.

London, December 16, 1910.

The distribution meeting of King Edward's Hospital Fund was held on Wednesday, and was of more than usual interest. The Duke of Teck presided and gave a most clear analysis of the work of the fund during the year, a statement on several questions that had been under consideration, and a summary of the several reports which were brought forward and adopted. He read a letter from the King, expressing his Majesty's unabated interest in the fund he had presided over for nine years, and his appreciation of the services which the council, committees, and officials rendered to the sick poor. The president mentioned that the King had raised his annual subscription from £500 to £1,000, that the Prince of Wales had become a subscriber of £100, that an anonymous donor had given £10,000, and Mr. Walter Morrison an annual £5,000. Altogether, the total income had passed for the first time £150,000, and that sum was allotted to the several hospitals, and in addition a £5,000 to santoria and convalescent homes. The Duke said that in regard to

grants for special purposes the fund requires a scheme to be submitted in every case. This is examined by a committee, and the fact that many grants are made shows that the hospitals do not propose unreasonable schemes for locking up money in bricks and mortar.

The scheme for placing beds at sanatoria by grants from the funds at the disposal of London hospitals has taken practical effect, and on January 1, next, eighteen beds in three sanatoria will be so occupied. They will be allotted to the two consumption hospitals which have no country branches and to two of the largest general hospitals. More beds could not be secured without capital grants, but sanction was now given to consider whether such a course would be advisable if the scheme on its present scale proves successful.

The executive committee has had under its consideration the question of hospital contracts in view of suggestions in various quarters that joint contracts would lead to economy in purchasing. The hospitals have been rather severely criticised in this matter, and a scheme of the kind having been started in New York a sub-committee was appointed to inquire into the subject. A report of this committee which has now been prepared will be at the service of any of the hospitals trying or proposing to try this method.

Last March the King, who was then president of the fund, expressed a hope that a committee of inquiry into the out-patient question would be appointed before the close of the year. The services for this purpose have been secured of Lord Mersey, Lord Northcote, and the Bishop of Stepney. These commissioners will investigate and report as to the circumstances under which patients are admitted to the casualty and out-patient departments of the London voluntary hospitals, and especially as to whether adequate provision is made for the admission of such persons as are suitable; or will make such recommendations as may seem to them desirable. Their report cannot fail to be of importance to the profession.

Another important subject connected with hospitals is also dealt with in the fund's report, viz., the financial relations between hospitals and medical schools. You will perhaps recollect that allegations have been made during the last year or two by persons whose chief contribution to hospitals seems to be charges of mismanagement, that payments were made to the schools or their laboratories out of subscriptions intended for the benefit of the patients. A committee was appointed on this matter which was presided over by Sir Edward Fry. The report of that committee laid down principles by which the fund intimated in March, 1909, it would be guided, and which it has been obliged to reiterate a week or two ago on account of fresh allegations made against one of the hospitals (St. George's). The point is not so much the general services rendered by a school to a hospital and *vice versa*, which may be taken as mutually valuable, but payments made on the part of hospitals for specific laboratory examinations for the purpose of helping the staff to form correct diagnoses and which would have to be paid for if made elsewhere, and, I may add, were paid for to other laboratories for hospitals to which no school is attached. The distribution committee have marked their opinion by recommending a continuance of the grant for the present year, though they invite the hospital to submit further detailed accounts to prove that in accordance with the principles of Sir E. Fry's report the hospital is clear from any payment toward medical education.

In reference to the last-named subject a set of persons calling themselves the "radical federation" lately sent a letter to the King, which they began by asserting they made no apology for doing so. Of course, his Majesty's secretary forwarded the letter to the fund, which considered it in the statement above. The "radical federation" secured an advertisement. It seems to be concerned in another agitation against hospitals, which has reached the education committee of the County Council, where it has been alleged that the working classes are discontented with the arrangements made for the treatment of school children.

It was stated that so great was the resentment felt that a conference of the organizations of these classes was about to take place, with a view of starting an anti-hospital Saturday and Sunday fund campaign. The most dissatisfaction seemed to be that the children were now asked to pay something where they used to go free. So it would appear that these people consider the hospitals as their own property. Their children get free education, free meals, free medical supervision, and advice, under the name of inspection, and yet are ready for revolution if they are asked for pennies for treatment at hospitals or school clinics. If these leaders really represented the working classes their boasted independence seems to be vanishing in covetousness eulogized as socialism.

The annual report on the health of the navy was published on Saturday, and shows a continuous improvement. Invaliding and death ratios for the year were lower than the quinquennial average, and the average loss of service fell from 10.8 to 9.76 days per person. The daily ratio of sick men was 26.75 per 1000, a decrease of 2.84 in comparison with the five previous years. The ratio of those invalided shows a decrease of 4.3 over that of the same five years. Of the invalids the ratio of 16.42 per 1000 were for disease and 1.38 for injury. The total number of deaths was 362, giving a ratio of 3.21 per 1000, a decrease of .54 compared with the preceding five years. Of this number, 2.28 per 1000 died of disease, and 92 per 1000 died from the results of injuries.

Dr. J. C. G. Ledingham has compiled and analyzed the various investigations concerning typhoid carriers that have been made at home and abroad, and his report appears in the public health and medical series of the local Government Board. Dr. Thomson, presiding at the epidemiological section (R. S. M.), on the 14th ult., referred to this work, in which he joined Dr. Ledingham. If the calculations of some bacteriologists were to be accepted there would be perpetual danger from this source, but although in some places and during epidemics the number of carriers has been estimated as very great, that cannot be the case in the general population, for the prevalence of the disease has been for some time decreasing. Many carriers cease to be so in about three months, but a percentage of these fever cases continue longer—an indefinite period—and are chronic. In a mixed population it has been estimated that 3 per 1000 would be possible carriers. If so, there must be many circumstances to restrict their potential infectivity.

Dr. W. Robertson, M. O. H. for Leith, describing to other officers of health the methods of controlling tuberculosis, said a great factor was education. His lady health visitors had zealously taught the doctrine

of open windows, and a great change was to be observed since the citizens were called upon to practise what they were taught. Their keenness had increased since compulsory notification had been adopted. In Leith isolation wards some patients had been kept nearly a year, and had been taught to assist the staff. One intelligent sailor had been helping in the laboratory, which he kept tidy and where he made the serum, and was able to offer provisional diagnoses. As to this last statement, other doctors may have some serious criticism to offer.

The value of sulphur as an intestinal disinfectant has been urged in the therapeutical section by Professor Wild of Manchester, who attributes its ancient reputation to the formation of H_2S, to which may be due the efficiency of the drug and of sulphur waters in gout, rheumatism, skin affections, and so on. Sulphates may be to some extent reduced in the bowel to sulphides and the preponderance among edible vegetables of those which contain sulphurous volatile oils is remarkable. The crude drug is tasteless, passes through the stomach without decomposition, and liberates H_2S in the intestines. It is a cheap laxative. If long continued it is apt to cause depression. One may add that a small quantity of the less oxidized gas is also liberated in the intestine and this, of course, is a decided disadvantage.

Mr. E. M. Holmes, whose intimate knowledge of botany and natural history is so extensive, has directed his attention to the possibility of preventing the spread of sleeping sickness. He mentioned at the pharmaceutical society on Tuesday that the tsetse is in the chrysalis stage during the cold months, so that the time to attack it is just before and just after that period. The larvae only enter the soil a short distance, or are deposited in the forks or at the roots of plants where the dead foliage or debris collects, so that fire at the surface along the few yards to which the fly usually extends from the shore should destroy a great number. Just outside this zone, he thought, plants like tobacco and that which forms the Dalmatian insect powder might very well be grown and utilized as soon as the flies appeared in numbers after the cold season. The flies, he also said, disliked any powerful odor, so camphor or sulphur might be carried about the person. He also ventured on what seems a less justifiable suggestion—the internal use of copper and quassia, copper being a powerful insecticide and especially destructive of algal life. It had been long known that workers in copper and brass show a very decided resistance to many diseases and a metallic odor is often exhaled in their breath—a fact confirmed in the last cholera epidemic.

Mr. William Henry Horrocks, senior surgeon to the Bradford Royal Infirmary, died on the 9th inst., aged 43. He was educated at University College, London, and at Owen's College, Manchester. He took the F. R. C. S., Eng., and M. B., Lond., with honors, in 1886. He led a most strenuous life in Bradford, and will be deeply lamented by his brethren and by the poor. He had been president of the local medical society, to which he contributed numerous important papers. He also contributed to literary journals. He was one of those energetic men whose activity enables them to carry on general practice and hospital work concurrently—one, too, whose brethren were never afraid to call into consultation.

OUR LETTER FROM PARIS.

(From Our Regular Correspondent.)

EXOPHTHALMIC GOITER—SURGICAL TREATMENT OF DUODENAL ULCER—TREATMENT OF VARICOSE VEINS—URINARY TUBERCULOSIS—FRENCH SURGICAL CONGRESS—DEATH OF ARMAND TROUSSEAU.

PARIS, December 15, 1910.

THE Annual French Congress of Surgery was held at Paris, October 3-8, 1910. The first question for discussion was the surgical treatment of exophthalmic goiter. The reader of the paper was Delore of Lyon. Exophthalmic goiter results from two causes: a thyroid lesion and a nervous lesion. Surgeons attack sometimes one, sometimes the other. The operations which have been done for goiter are thyroid operations, which consist in the ligature of thyroid arteries and thyroidectomy. Thyroidectomy should be only partial so as to avoid cachexia strumipriva; we must preserve a portion sufficient for function and in good condition. Subcapsular hemithyroidectomy is the operation that should generally be done. After the operation there is seen an early and immediate phase of improvement of the subjective troubles and tachycardia. This is one of the most remarkable effects of the operation. Later we see also a slow and progressive improvement of the subjective symptoms and a definite cure. An ideal recovery demands a relatively long period; it occurs in not less than six months to two years. The operations which are directed toward a nervous lesion in goiter are summed up in sympathicectomy. This operation consists in the resection of the cervical sympathetic, and is defended by Jaboulayee of Lyon, and Jonnesco of Bucharest. As a result of this operation we notice an immediate relief of the exophthalmos; the goiter diminishes, but much more slowly; the subjective condition also improves. Still the effects of sympathicectomy are inconstant. Lenormant of Paris, was a speaker on this same subject. He believes that the action of surgery cannot be supplemented in the treatment of goiter either by radiotherapy or by medical treatment. Thyroidectomy is the only method in which one may have confidence, because it is the only one which has given proofs of a complete and prolonged cure. Lenormant believes that when the physicians send to the surgeon only cachectic and almost desperate cases, as too often happens now, surgeons can make only murderous and useless operations. Exophthalmic goiters must be operated on early and with a good general condition present.

Doyen of Paris thinks that the only operation to be practised for exophthalmic goiter is thyroidectomy, which, if it is done rapidly, in a few minutes, is harmless, and exposes the patient to no serious accidents. Jonnesco of Bucharest thinks, on the contrary, that treatment of the cervical sympathetic is the best treatment in exophthalmic goiter. Kocher, of Berne, thinks that the operation of thyroidectomy demands much minute work and prudence, but that with these precautions one may get a mortality of only 2.06 per cent. in 637 operations.

The second question in order of discussion was the surgical treatment of duodenal ulcer. Those who considered this question were Ricard of Paris, and Pauchet of Amiens. Ulcer is not generally recognized except when complications occur. The most frequent of these complications is hemorrhage, which may appear as hematemesis or melena. Again it is by the symptoms of stenosis, or perforation, that the disease shows itself. The treatment of

duodenal ulcer is purely surgical, for medical treatment brings about only an imperfect cure. Every duodenal ulcer should be operated on, and there are four methods of operation offered to the surgeon: excision, gastroenterostomy, resection, and exclusion. The operation of choice seems to be gastroenterostomy. The low mortality which the operation gives in the hands of experienced surgeons, and in subjects not yet cachectic, should encourage the physician to accept the opinion and the treatment of the surgeon, that operation is the only treatment applicable to duodenal ulcer.

The third question of the day was immediate and remote results of bloody operations in the treatment of varices of the lower limbs. Jeannel of Toulouse, and Mauclaire of Paris were the speakers. Jeannel recalled the fact that in the genesis of varices there are two different elements; a biological element which determines the histological lesions of the venous walls, and a physical element which is the hydraulic pressure of the blood. It is only against the latter that surgery can effect anything. The success obtained by each of the operative methods is incontestable. But one should only demand of each of these methods what it can do. First of all must be solved a question of diagnosis; if it is solely the superficial reflux that is the cause one should practice a ligature of the internal saphenous vein of the thigh (Trendelenburg operation); if it is the deep reflux which is the cause one should have recourse to excision of the different masses of veins of the leg and the thigh; if the two refluxes, superficial and deep, have a parallel rôle, it is total saphenectomy that should be done.

Transvesical ptostatectomy was treated by Luys, who presented a series of prostates removed by operation with cure of the patients. To preserve for this operation its benignity in mortality he enumerated the precautions that should be taken before the operation and after it.

Before the operation there should be a complete analysis of the urine, a careful examination of the prostate and the bladder under the control of the eye and the cystoscope, and the disinfection of the bladder as complete as possible by appropriate lavage. After the operation one should apply to the patient, after a large Freyer drain, an apparatus for collecting the urine over the hypogastric wound, which allows the patient to get up the eighth to the tenth day. This collecting apparatus allows a complete surveillance of the wound, the washing and disinfecting of it without moving the patient. This will keep in place during the night and the patient may turn on his side without being wet. Among the other complications Luys especially mentions late infection, which he treats by copious urethro-vesical washing without a sound, and strictures of the membraneous urethra, which he advises to treat not by an external urethrotomy but rather by the urethral route. In one case he was able to reestablish the complete permeability of the urethra by practising under the control of the eye, with the urethroscope, a catheterization which would have been absolutely impossible under other conditions.

Newmann of Glasgow spoke of renal and vesical tuberculosis. According to him there is great danger of allowing the first symptoms of renal tuberculosis to pass unnoticed. The methods of exact exploration are to-day very perfect, and allow a precise diagnosis. The treatment by tuberculin not having succeeded, it is to nephrectomy that one must turn.

The ablation of the seminal vesicles was discussed by Villard of Lyon. The author considers the abdominal as the method of choice in removal of the seminal vesicles. He recommends an incision following first the inguinal canal throughout its length, then reaching up to the umbilicus, following the outer border of the rectus muscles. This incision allows one to separate the peritoneum high up and to extirpate the seminal passages in all their length, commencing from below.

The twenty-fourth French Congress of Surgery will take place in Paris, in 1911. The vice-president of the congress—who will be president in 1912—is the eminent Professor Delorme, who occupies the highest medical position in the army. The three subjects discussed will be the following: (1) Diagnosis and treatment of chronic appendicitis. (2) Treatment of acute peritonitis. (3) Open treatment of closed fractures.

Dr. Armand Trousseau, grandson of the illustrious clinical professor of the Hotel-Dieu, was a victim of a terrible automobile accident which cost him his life. The eminent practitioner drove his own carriage at high speed; it turned over and he received a fracture of the skull which caused instant death. Armand Trousseau was interne of the Paris hospitals, and specialized as an oculist. Physician to the *Hospice des Quinze-Vingts,* he drew by his clinical acumen and his successful operations a very large and successful clientèle. Armand Trousseau was well known in Paris society, where he had many friends. He was a fervent automobilist. His hardihood and passion for the sport cost him his life, but his sudden exit profoundly saddens those with whom he was intimate, and the crowd of patients who had confidence in his skill.

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

NON-OPERATIVE TREATMENT OF CANCER — COLEY'S METHOD IN SARCOMA—AUTOVACCINES IN CARCINOMA—ABSENCE OF TOXINS FROM COLEY'S FLUID—COMPLETION OF THE NEW STATE HOSPITAL AND MATERNITY.

COPENHAGEN, November 28, 1910.

AFTER a long resting period during the summer the Medical Society of Copenhagen has returned to its scientific work, and the first meetings of the new season have been very interesting. Professor Thorkild Rovsing, the well-known surgeon, introduced a discussion on the non-surgical treatment of malignant disease. Two lines of treatment, for a time very widely used, viz., the trypsin treatment and the fulguration after de Keating-Hart's method, he considered as utterly exploded. While he regretted that he had been led to try the former one, not without disastrous results, he rejoiced in the fact that he had never wasted the money of the University clinic on a fulgurating apparatus. *X*-ray treatment without doubt cured a great many rodent ulcers, but cases of deeper seated carcinoma did not, as a rule, benefit by this treatment; on the contrary, the patients not seldom became worse. A certain number of patients suffering from sarcoma were definitively cured by *x*-ray treatment. As an instance he mentioned a case treated four and a half years ago of inoperable osteosarcoma of the cranium, involving the dura mater and cerebral substance, and complicated with epileptic fits. Not only had the wound healed beautifully after a quite insufficient extirpation of the tumor masses, but the epileptic fits had ceased.

As for the treatment by toxins of the erysipelas microbe he expected not a little success from it. He remembered particularly a case of inoperable sarcoma of the arm which he treated many years ago by inoculation of a pure culture of erysipelas streptococcus. Following the second inoculation the patient developed a most marked erysipelas, spreading from below up above the tumor, with great tumefaction of the surrounding tissues, which eventually burst asunder, whereupon the tumor was expelled spontaneously. Unfortunately, the patient died from an intervening hemothorax. The postmortem examination revealed the highly interesting fact that the patient had suffered from metastases in the lung, and the lung tissue had now burst around the metastases in the same way as the arm tissue around the primary tumor. He considered it an undoubted fact that Coley had succeeded in curing many sarcomas by his injections, but he himself had personally only observed failures from the use of Coley's fluid. He thought the reason was that the injections, as furnished from the laboratory, contained no erysipelas cocci proper, nor their toxins, but, as Coley himself stated, cultures of cocci from a case of septicemia together with *Bacillus prodigiosus*. Now Coley had told him that he (Coley) considered the effect of the injections to be due to the *Bacillus prodigiosus*, but as the clinically well authenticated "spontaneous" cures of sarcoma had all been observed during an intercurrent attack of erysipelas Rovsing thought that the toxins of erysipelas, and not those of other streptococcic diseases, ought to be employed.

Since September, 1909, Rovsing had entered upon another line of non-surgical treatment of malignant tumors, viz., the vaccination treatment, using as injections a fluid obtained from the patient's own tumor. He would not discuss the etiology of malignant disease, but he stood strongly on the side of the infection theory. Of course it was too soon, and the clinical material as yet too small, to judge of the eventual success or failure of the experiment, but he was inclined to think the results encouraging in the sarcoma cases. On the other hand, judging from his ten cases, carcinoma did not seem to be influenced by the vaccination treatment. Of seven sarcomas treated two seemed to have benefited remarkably by the treatment. The first case was an inoperable recurrence of sarcoma in an amputation stump; this was only scraped out, and as a result of the vaccination treatment the wound healed rapidly, while a metastatic inguinal gland tumor disappeared totally. The patient had now remained free from recidive for more than a year. The other case was a melanosarcoma of the liver, treated by resection and subsequent vaccination.

Professor Salomonsen congratulated the speaker on his results. As to the desirability of choosing only cocci from cases of clinically typical erysipelas for the toxin treatment, he was not sure that it was necessary to do so. In his opinion other streptococci might be equally efficient.

Dr. Thorwald Madsen, director of the State Serum Institute, said that it was quite probable that no erysipelas toxins would have been present in Coley's fluid, even if erysipelas cocci had been used for its production, as the method of elaboration employed tended to destroy the said toxins. He therefore thought that what effect might have been observed from its use must be ascribed to the presence of prodigiosus products.

Since I wrote you last the new State Hospital and Maternity (Rigshospitalet) has been handed over to the medical faculty of the Copenhagen University. It accommodates about eight hundred patients, and ranges certainly among the very best-equipped medical institutions in Europe. American doctors on voyage in Germany would not regret a visit to Copenhagen, where they will be sure to meet always with a cordial welcome. It is only eight hours distant from Berlin.

DR. WOODS HUTCHINSON'S PROGNOSTICATIONS.

To the Editor of the Medical Record:

Sir:—In *Hampton's Magazine* for last November, Dr. Hutchinson appears as the author of an article entitled "The Passing of Pills and Powders." After reading this remarkable production I sent a few questions to the "Current Comment" department of *Hampton's* asking that they be inserted as soon as convenient. After detaining my very brief communication for over a month it has been returned with an intimation that space cannot be found for it. Believing that my questions are of some interest to the medical profession, I take the liberty of asking you to publish them.

On page 661 (of November *Hampton's*) Dr. Hutchinson says, in italics, "No drug—save quinine and mercury in special cases—will cure a disease: only rest, food, sunshine, and fresh air can work that miracle." Again, on page 664: "We no longer believe that any drug, of itself alone, will cure any disease."

Gonorrhea is about as common as any disease. It is usually admitted that a large percentage of the male population of the United States suffers from it at some stage of earthly existence. The only cases that are *cured* in the true sense of the term are those that get into the hands of an ethical specialist. Does Dr. Hutchinson believe that gonorrhea can be cured by fresh air, sunshine, etc., or by some form of mercury, or quinine, or both?

Page 660: "Emetics are being replaced by the stomach tube; cathartics by dieting and intestinal antiseptics" . . . "Antiseptics will one day do as wondrous service for medicine as they have already done for surgery. . . ." Are not intestinal antiseptics drugs? If not what are they? If they are drugs, does not the doctrine of their "wondrous service in the future" conflict with Dr. Hutchinson's opinion that drugs do not cure any disease, and that their use is "passing"?

Digitalis, glonoin, nitrite of amyl, codeine do not cure disease, but they relieve suffering, and sometimes prolong life. Does Dr. Hutchinson consider that their day is "passing," and that "rest, food, sunshine, and fresh air" will take their place, or does he believe that the diseases which they alleviate will gradually—or suddenly—disappear?

Buffalo, N. Y. Lawrence Irwell.

Infantile Diabetes.—Pierre Maurel says that diabetes is not very rare in infants, but diagnosis is often not made. The type is that of a severe pancreatic diabetes. The symptoms are polyuria, polydipsia, and polyphagia, with severe glycosuria. Emaciation and digestive disturbances are attributed by the mother to gastrointestinal conditions, and no urinary examination is made. In nursing children a teaspoonful of vichy is given after each nursing; in older children with artificial feeding the milk is sweetened with mannite, glycerin, or saccharose. No gruels are given, but as soon as possible beef broth and eggs. Vichy is used after each meal.—*Annales de Médecine et Chirurgie Infantiles.*

The Care and Management of the Tabetic Bladder. 1. Diagnosis. J. D. Barney.
Bilharziasis; Report of a Case with Appendicitis; Literature since 1904. C. G. Lane.
Tuberculosis Amongst the Philippine Scouts (Native Troops) of the United States Army. J. W. Brewer.

The Tabetic Bladder.—J. D. Barney presents the following conclusions: 1. Trabeculation of the bladder in tabes is found in more than 80 per cent. of cases and may occur before any symptom or other sign of vesical disturbance. 2. In tabetic bladders it is found in the fundus and side walls only, in typical cases. It is more delicate and regular than that seen with mechanical obstruction. 3. It is probable that it is due to a primary detrusor hypertrophy. 4. Residual urine is found in more than 70 per cent. of cases, often before any symptoms begin. 5. In over 50 per cent. of all cases the urine is infected. 6. Cystoscopy is generally a painless procedure, a fact which is of some diagnostic value. 7. Urinary disturbances, variable in character, are observed in over 90 per cent. of all patients with tabes.

Bilharziasis.—C. G. Lane reports a case of both intestinal and genitourinary bilharziasis with terminal spines on all the ova seen, and complicated with an acute appendicitis, with operation and recovery, sections of the appendix showing many bilharzia ova in the wall. A review of the reported cases brings out the fact that there are only five undoubted cases of the South African bilharzia hematobia among them. In the last five years more evidence has been advanced for the skin infection theory. Investigation shows that the lateral spined ova may belong to one species of bilharzia and the terminal spined to another.

Tuberculosis Among the Philippine Scouts.—J. W. Brewer states that tuberculosis, although causing the largest mortality, has probably received less attention than any other disease that afflicts the inhabitants of the Philippine Islands. In the city of Manila it causes about 14 per cent. of the deaths, and the death-rate is 538 per hundred thousand. Just how much sickness it causes amongst the native population is difficult to ascertain from the data available. It is believed that most of the cases of tuberculosis amongst the Scouts are contracted in the "soldiers' barrio," which is located on the outskirts of most of the posts. Nearly every Scout is either married or lives with a native woman. It is the custom to allow the men, when not on duty or "restrictions," to sleep out of barracks. In most instances, the company commander assures himself that the houses occupied by the families of his men are reasonably clean before he will allow them to sleep out, but these buildings are nearly always deficient in ventilation, especially during the night; and as most of the houses in the Philippine Islands harbor a consumptive it is safe to assume that nearly all of the homes of the Scouts are infected with tubercle bacilli. A great step towards the prevention of tuberculosis amongst our native troops would be to move "soldiers' barrio" on to the reservation, so that it may be under military control. It would then be possible to see that the houses are properly ventilated, and to guard against the introduction of cholera and similar diseases. If this cannot be done, much good can be accomplished by making frequent inspections and restricting those men whose families do not comply with the sanitary regulations. Under no circumstances should the barrio be abolished, nor should any restrictions whatever be placed upon the marrying of the scouts, because it keeps them free from venereal diseases which prevail most extensively among the white troops.

The Law of Degeneracy in its Relation to Medicine. C. P. Noble.
Psychotherapy—Its Uses and Abuses. E. D. Fisher.
Pulmonary Tuberculosis as Studied in the General Medical Dispensary. E. J. G. Beardsley.
Ear Disease and its Prevention. A. Bardes.
The Prevention of Abortion. C. Rosewater.
Removal of the Faucial Tonsil Followed by Graves' Disease. C. J. Koenig.
Liquid Air and Carbonic Acid Snow. J. D. Gold.
The Dislocated Puerperal Uterus. W. L. Marsden.
Magic and Medicine. J. Knott.

Degeneracy.—C. P. Noble states that degeneracy may be acquired as well as inherited. A bad environment may arrest the development or evolution of the growing child of normal ancestry and result in developmental hypoplasia. The condition is similar, if not identical, to that when it is of hereditary origin. The acute infections, bad sanitary conditions and malnutrition the result of improper food, are among the chief causes of acquired degeneracy or arrested evolution. In the case of children and young adults this point is emphasized, in order that it shall not be inferred that developmental hypoplasia is always hereditary in origin. In the adult the chief causes are overindulgence in food and drink, sexual excesses, and overwork, in addition to those causes operative in the young.

Psychotherapy: Uses and Abuses.—E. D. Fisher states that obsessions of the condemnatory type, delusions of the paranoidal type, persistent phobias, from which the patient prays to be delivered and tries to deliver himself, are supposed to be the especial field in which the psychotherapeutist is eminently successful. By psychoanalysis the original thought, act, which perhaps preceded the special obsession, is searched for in the patient's mind. It is probably unknown to the patient himself, but by association may be evolved from the distant forgotten past. This may be hastened by partial hypnosis. It is supposed that the finding will relieve and does relieve the existing obsession. There is great room for deception here. That improvement often takes place in these cases cannot be denied, but it may possibly be explained by the attention given the patient, the evident interest in and desire to help manifest by the manipulator. Or, again, the opportunity thus given the patient to reason out by this aid and help the mental process which has produced what is even evident to him is not the usual process of reasoning in his friends and acquaintances. He tries to analyze with this aid why he feels and thinks so differently than previously, and thus, provided no permanent disorganization of cell structure has taken place, there may be recovery. This probably would have occurred in time in any case under the physician's care. Psychotherapy, therefore, seems an unnecessary and labored process and one open to much error and fraud, and when, as often is the case, it is carried on by inexperienced persons, it results in permanent injury to the individual so treated.

Dispensary Treatment of Tuberculosis.—E. J. G. Beardsley concludes that work at the dispensary has taught him several things. 1. In the first place, that even now after all the publicity that has been given the subject of tuberculosis the disease is not, among the people that suffer from its effects to the greatest extent, recognized until it has persisted for months, if not for years, and not until all reasonable hope for a cure has passed. 2. That the failure of the physician to diagnosticate the condition is in great part due to his failing to have the patient properly prepared for examination—that is, stripped to the waist. 3. That the simple precaution of taking a temperature before pronouncing a patient free from tuberculous disease is not used by those physicians who would benefit most by its use. 4. That the same may be said of that most valuable aid to diagnosis in chronic pulmonary conditions, auscultation during deep breathing after the patient coughs. 5. That with the rarest exceptions dispensary patients (as seen in an ordinary medical

dispensary) are a danger to the health of those living with them because of their habits of life, and that all the supposed healthy members of the family should be carefully examined, and frequently re-examined. 6. That a large number of tuberculous patients for many years to come will be compelled to receive their treatment at home. 7. That the medical dispensary (unless special arrangements can be made) is a very undesirable place to treat the tuberculous patient. 8. That the essentials for a dispensary for the tuberculous have been well stated by Cabot, when he said that what was needed was (a) a physician who knows the disease thoroughly and is willing to give his time for a few hours a week to the examinations of suspected patients and the general supervision of their treatment; (b) a nurse or trained visitor, preferably a trained social worker who is also a nurse and who understands tuberculosis work, who will go to the home of the patient and see that the details of the treatment are properly carried out; (c) finally, for the support and guidance of the undertaking, an antituberculosis association, whose members can collect between $750 and $1,000 a year.

Ear Disease.—A. Bardes states that the otitis due to grippe is perhaps the most troublesome form one has to contend with. Very often it develops suddenly, with severe deafness and sharp pain. Hearing tests with the tuning forks show diminished conduction, both by air and bone—an evidence of internal ear implication, and a circumstance that adds to the gravity of the complaint and frequently interferes with the return of the hearing. As the years roll by the grippe ear increases in frequency, probably because we are becoming more and more enervated by our artificial ways of living. As a rule, in the course of a general infection, the ear does not become diseased until the second week, when the fever is declining and the relaxed blood vessels are pouring out their exudate, at a time when the vitality is low, and the resistance is poor.

Prevention of Abortion.—C. Rosewater states that cases of criminal abortion should be dealt with cautiously, yet firmly. Cautiously so that innocent parties are not accused, otherwise irreparable damage may be done them. Firmness is required where the evidence of guilt is positive, and in these cases the laws should be invoked that the guilty parties may be punished. Publication of all cases of abortion, miscarriage, or premature labor has been advocated by some as a good measure to hold this nefarious practice in check. By this means the origin of these cases can be traced, and those known to be regular abortionists should have their licenses revoked. Impending abortion or miscarriage can be checked only by insistence on absolute bed rest, the use of uterine sedatives, and the avoidance of all local instrumentation. If, however, the fetus is already presenting in the widely opened os the abortion is inevitable and can no longer be checked. In order to prevent abortion physicians should also be careful to teach their pregnant patients the hygiene of pregnancy, the care of the body, the necessity of avoiding violent exercise of all sorts, such as dancing, horseback riding, automobiling, jumping, or running. Tight lacing should be avoided. From the time pregnancy sets in all sexual intercourse should be prohibited. The patient should be made to understand that upon the proper supervision of pregnancy all through its course very much depends, not only as regards her health, but also as regards that of the offspring, and she should especially be impressed with the importance of immediately seeking her physician's counsel when a disturbance of the natural course of things occurs. Women should be instructed as to the dangers of interfering with nature, and that such interference in pregnancy is followed nearly always by impairment of health. Physicians should be careful not to introduce a sound, or any other instrument, into the uterus where pregnancy may possibly exist. Operations on the genitals or pelvic and abdominal organs should be avoided during pregnancy unless they are done for the saving of life, cannot be postponed, or are done for the purpose of removing conditions which would render the childbirth more hazardous. In some of these cases a delicate and accurate balance of judgment is necessary to do what is best for the case. In treating all gynecological cases careful and repeated examinations should be made in order to avoid mistakes in diagnosis before treatment is instituted. Such mistakes where pregnancy exists may lead to the slaughter of the innocent and bring discredit if not disgrace to the physician.

Tonsils and Graves' Disease.—C. J. Koenig states that it is impossible to say that there exists a causal relation between the removal of the tonsils in the case which he reports and the symptoms of Graves' disease which followed, but if this relation really exists its pathogenesis will be difficult to explain, especially as pathologists do not agree as to the cause of Graves' disease, some considering it a primary secretory disease of the thyroid, others attributing it to a disturbance of the nervous system. Could it be possible that the surgical shock and the traumatism of the terminal filaments of the sympathetic or other nerves in the tonsils produce Graves' disease in a person predisposed to that affection? It is also quite possible that the repeated throat symptoms presented by this patient may have been forerunners of the symptoms of exophthalmic goiter.

Liquid Air and Carbonic Acid Snow.—J. D. Gold states that the cases most advantageously treated by these agents are vascular nevi. The so-called port wine marks are not as favorable cases, as nevi, cavernous in character, pigmented nevi, light or dark, with or without hairs, yield to the applications. Lupus erythematosus carefully and persistently treated will be cured. Epithelioma of the skin, the more recent the growth, the greater the chances of a permanent cure. Epitheliomata of the lip yield marvelously to the applications, but how permanent the cure remains for future observation. Tuberculosis verrucosis cutis, verruca, and similar superficial growths are all favorable cases for treatment. In the past treatment of these disease with caustics (nitric, carbolic, or trichloracetic acids), electrolysis, curette, excision, etc., by the dermatologist has been so many times disappointing that anything new is hailed with delight, and especially so as experience has shown that success beyond expectations crowns one's efforts in relieving the sufferers of these disfiguring and malicious growths.

Dislocated Puerperal Uterus.—W. L. Marsden states that in primaparæ with relatively large pelves, in multiparæ with relaxed abdominal parietes, relaxed pelvic outlet, and overstretched uterine supports, the uterus may be readily forced into the pelvis by such straining efforts as vomiting, coughing, the frequent defecation of hypercatharsis, especially in upright position over the chamber vessel, too early getting up, etc. When such descent of the uterus occurs, more or less impaction of the organ is liable to take place; alarming hemorrhage may result; the circulation through the uterus is impeded; edema ensues, increasing the impaction; the flabby cervix, and often the lower uterine segment, is acutely flexed upon the rounded ball of the uterine body, occluding the cervical canal, and obstructing the flow of the lochia; distressing after pains occur, with tender abdomen, and weight and bearing down in the pelvis; the patient is excessively nervous, has headache, and within a few hours, if unrelieved, has a rising temperature, from the inadequate drainage of the uterus.

Magic and Medicine.—J. Knott continues his article on this subject.

Protein Diet in Nephritis.—H. D. Arnold presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1072.

Appendicitis in Childhood.—H. C. Deaver states that the number of cases of this disease increases in frequency with age from birth to puberty, and it is more common in males. The course is more often severe than in adults. There is less tendency to formation of strictures, but fecal concretions are more frequent. As predisposing causes he mentions enteric fever, intestinal catarrh, and influenza, but other infections and nasopharyngeal trouble are hardly to be considered as etiologic factors. The symptoms in infants are often scanty, irregular and misleading, and the disease is more frequent than the statistics show. In older children acute attacks occur suddenly with stormy symptoms even more frequently than in adults. Chronic appendicitis indicates a focus of chronic autotoxemia, with all its bad results. He believes that all cases of abdominal trouble in children should be considered appendicitis until proved otherwise. The differentiation should be made with intestinal catarrh or worms, right-sided pneumonia, or sacroiliac disease, torsion of ovarian cysts, mesenteric cysts, cystitis, and rectal abscess. With early diagnosis and operation the prognosis is favorable, but it rapidly becomes worse after twenty-four hours. In chronic appendicitis an acute attack with perforation is always to be feared. In intra-appendiceal appendicitis complete removal of the appendix and the diseased surroundings is advised. Non-operative treatment is indicated in localized abscess with diffuse peritonitis. Opium and purgatives are absolutely contraindicated. Operation is even more suitable to children than to adults, and postoperative treatment is very important. The Fowler position must not be kept up for more than thirty-six hours in drainage cases, lest intestinal obstruction be set up. The symptoms of obstruction are sudden severe pain, becoming paroxysmal, and nausea, spitting up, and vomiting. Later symptoms result from toxic peritonitis. The temperature and pulse are of little significance. With numerous adhesions, ileocolostomy is the best procedure. Secondary abscess must be watched for. Its presence is revealed by a rising and continued high temperature, with a high leucocyte count and local signs. Contagious diseases should be recognized at once. Drainage is to be employed only when the exudate is purulent or profuse. It produces adhesions and predisposes to intestinal obstruction. A wet dressing is the best for absorption.

Patent Ductus Arteriosus.—K. C. Mead presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1071.

Chalazion.—R. S. Lamb describes a simplified operation for this condition.

Sodium Cacodylate in Syphilis.—H. J. Caffrey reports a case of syphilis, with a chancre of the lip as the primary lesion, in which after nineteen days of treatment by means of hypodermic injection of this drug all traces of the disease had left the patient.

Deltoid Paralysis.—D. D. Lewis describes his operation for the correction of the motor disturbances associated with deltoid paralysis, by means of transplantation of the trapezius muscle.

Congenital Dislocation of the Shoulder Joint.—V. F. Huntley reports a case of this condition.

Sporotrichosis in America.—R. L. Sutton states that the affection is more common than the statistics would indicate. If care were taken, however, diagnostic mistakes would be less frequent. A trauma of the hand, forearm, or leg, resistant to ordinary surgical treatment and accompanied by abscesses along the course of the limb, should always arouse suspicion, especially if symptoms of streptococcus cellulitis are absent. Two cases are reported.

Conservative Surgery of the Pelvic Organs and the Lower Abdominal Wall.—F. McRae presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1108.

Intestinal Indigestion in Children.—S. M. Hamill and K. D. Blackfan state that in the routine examination of the stools of apparently normal children foul smelling feces, sometimes containing particles of undigested food, are a common finding. Closer examination will often result in the discovery of other symptoms of disordered digestion, of which the child has made no complaint. Nevertheless, this one symptom may continue indefinitely as the only one, and this is important, as it is the best time to treat it early. The only satisfactory way of making the diagnosis of these milder forms is by the routine examination of the stools, and this should be done several times at intervals of several days. Aside from the stools, the symptoms may vary from nothing to a very serious clinical picture and are by no means restricted to the intestinal tract. The cardiovascular system may be most affected, and on the part of the nervous system there is no limit to what may be observed. The most common nervous phenomena are restless sleep, night terrors, and sometimes insomnia. The authors call especial attention to the restlessness and irritability, sometimes culminating in convulsive attacks which may be the foundation of future epilepsy. It is difficult to explain why certain children show more marked nervous symptoms than others, and the authors think that the term neurasthenia may be properly applied to these nervous symptoms dependent on the toxins developed by intestinal indigestion. Distention of the abdomen does not develop in all instances, and, when vomiting of toxic origin also occurs, the picture of tuberculous peritonitis may be strongly suggested and its exclusion be difficult. Another symptom especially mentioned is the peculiar form of dyspnea or "sighing respiration," most marked after meals, especially supper, or when food is taken immediately after severe exercise. The authors think one may attribute it to some toxic effect on the respiratory centers. The treatment divides itself into, first, absolute control of the case, *i.e.*, the full cooperation of the mother and nurse. This is essential for success. Second, hygienic measures, life in the open air, regulated exercise, slow eating and due mastication, early retiring and long hours of sleep; attention to the skin and excretions is important. Defective teeth must be attended to, as well as disturbing adenoids and tonsils. The diet should be well selected, according to the needs, and over-eating prevented. Drugs are of least importance. The intestinal antiseptics have not been of any use, but in the beginning of the treatment a course of calomel, followed by colonic washings, is effective. Drugs are seldom needed for constipation. The free use of water, regularity of habits and a selected diet will control this condition. As a temporary measure olive oil enemas and non-irritant suppositories are preferable to laxatives. Bitter tonics are the only ones that are needed.

Nitrous Oxide and Oxygen Anesthesia.—W. D. Haggard states that while nitrous oxide is the safest and pleasantest of all anesthetics, it is not absolutely free from danger. In overdosage death is caused by asphyxiation and cardiac inhibition. The danger signals with this anesthetic are: Deep and persistent cyanosis, depression and slowing of the pulse and vomiting. Cyanosis is the first of these and gives warning of impending danger, and discontinuance of the gas and giving of oxygen, which should always be at hand, promptly relieves the symptoms. Crile's investigations are referred to, showing that animals under nitrous oxide withstand shock-producing trauma much better than under ether, and their resistance when pathologic from infection, etc., is strikingly better under nitrous oxide. The cyanosis that is produced, through a warning, is not nearly so dangerous as that from ether or chloroform. The rebreathing of the gas is advocated, as the carbon dioxide produced acts as a stimulant, it is non-toxic up to the amount that would be taken in the short period for inducing anesthesia, and will, as a stimulant, act as a preventive to shock, while the rebreathing renders unnecessary the warming of the gas. Some patients, notably very robust and alcoholic individuals, cannot be sufficiently relaxed without disagreeable cyanosis. In these, ether given for three or four minutes will usually complete the anesthesia. Gas and oxygen can be used with impunity when ether is contraindicated, as in kidney disease. It does not apparently increase the mortality in advanced pulmonary cases and is specially useful in borderline cases of surgery in which other anesthetics would be unsafe. The chief contraindication to nitrous oxide is a heart lesion, myocardial or valvular, but it is admittedly more difficult to administer than ether, and is therefore less adaptable for the general practitioner. It is especially fitted for hospital use, where most of the major surgery is nowadays done. It can be given for a longer period with safety than any other anesthetic. A small dose of morphine and atropine makes the induction of anesthesia more easy, and Crile gives 1/150 of a grain or less of scopolamine about two hours before operation. The cost of nitrous oxide anesthesia can be greatly reduced by the use of the Gatch apparatus and rebreathing, and can be still further reduced in hospitals.

Anesthesia in Traumatic Surgery.—G. Torrance states that the majority of surgeons both here and abroad seem to give preference to ether over chloroform.

Ethyl Chloride Anesthesia.—H. C. Wood calls attention to the perils of the use of ethyl chloride as an anesthetic. While the statistics would seem to indicate that, as regards mortality results, ethyl chloride stands between ether and chloroform, but closer to the latter, this conclusion is unfair. The anesthesias by ethyl chloride have practically been all of but a few minutes' duration, and the prolonged anesthesias, which have to be credited with many of the fatalities of chloroform and ether, do not here come into consideration. The comparison should be rather with nitrous oxide gas. If one compare the commonly accepted mortality for nitrous oxide, one death in 1,000,000 anesthesias, with the figures for ethyl chloride, one in 6,000, the danger of the latter is evident. The safety of an anesthetic is to be judged by the range between the amount required to produce unconsciousness and that required to kill, and also by the character of the signs which indicate danger. These latter are for ethyl chloride, such as may be easily overlooked by any except an experienced anesthetist, and another danger is remarkable suddenness of the fatality when it occurs. The author considers the use of this agent by untrained persons as hardly less than criminal.

Autogenous Vaccines and Pulmonary Hemorrhage.—R. T. Pettit states that his investigations showed that in patients receiving vaccines the percentage of hemorrhage is only one-third of the percentage in patients not receiving vaccines. All patients were under exactly the same conditions of housing, feeding, and medical supervision. While it is not admissible to draw definite conclusions from the small number of cases reported, the results seem to justify the administration of autogenous vaccines in a larger number of cases as a protective measure.

Iodine for the Umbilical Cord.—J. S. Lewis states that the advantages of the application of tincture of iodine to the freshly severed stump of the cord are simplicity, increased rapidity of drying, and the penetrating, bactericidal power of the drug.

Measurement of Blood Cells.—P. A. Sheaff describes a simplified method for this purpose.

Hairy Tongue.—M. Leon describes a case of this condition, cured by scraping under local anesthesia and application of a 10 per cent. solution of mercuric chloride.

The Aftermath of Eyestrain. S. Stephenson.
The Specific Diagnosis of Pulmonary Tuberculosis. A. C. Inman.
Notes on Tuberculous Meningitis with Especial Reference to the Invasion Symptoms when the Disease Occurs in Adults. W. B. Warrington.
The Etiology of Beriberi. H. Fraser and A. T. Stanton.
Cases of Primary Carcinoma of the Appendix Vermiformis. A. M. Kennedy.

Eyestrain.—S. Stephenson states that whenever a headache, migraine, vertigo, or "tic" is induced or made worse by use of the eyes and relieved by rest one may safely assume it is due to eyestrain. Slight errors of refraction are most likely to cause distress in persons who have inherited or acquired an unstable nervous system. Headache is the commonest reflex manifestation of eyestrain. Of all errors of refraction, slight grades of hyperopia, and particularly of hyperopic astigmatism, are those most likely to cause distress. A large error of refraction leads, as a rule, to defective sight and not to eyestrain. Among the symptoms or conditions that may result from eyestrain, the author mentions, besides headache, insomnia, migraine, vertigo, functional neuroses, such as habit-spasm, and polyuria, epilepsy, phobias. Many other conditions have been assigned to the same cause, although not always upon adequate evidence. Among these conditions may be mentioned dysmenorrhea, tachycardia, sleepiness, enuresis, sea-sickness, night terrors, constipation, tinnitus, Ménière's disease, dermatitis, sinusitis, appendicitis, and pre-tuberculosis, to say nothing of head-tilting and spinal curvature, and, more startling still, of the drug habit, crime, insanity, and suicide. Some of these suggestions seem more than a little far-fetched.

Specific Diagnosis of Pulmonary Tuberculosis.—A. C. Inman concludes that in the diagnosis of early pulmonary tuberculosis the recent methods of concentration (antiformin) should always be employed for the exposition of tubercle bacilli in the sputum and feces. The difficulty of interpreting the results of the various tuberculin tests seriously limits their value in the diagnosis of active pulmonary tuberculosis. A positive opsonic index test is of undoubted value in the diagnosis of active pulmonary tuberculosis. A negative opsonic index test must be taken with reserve. The interpretation of the result rests with the clinician, who can take into consideration all the additional factors in the diagnosis of the case.

Tuberculous Meningitis.—W. B. Warrington states that this condition is met with chiefly as a terminal event in chronic pulmonary phthisis, in which it causes death in about 3.3 per cent. of cases. Several writers mention that when tuberculous meningitis occurs in adults the clinical picture may present unexpected features, misleading if the possibility of this condition is not remembered. Oppenheim, in describing the early delirium and mental confusion which soon occur, points out that grown-up patients

may go about in this stage and appear as if afflicted mentally; sometimes they are in a dreamy state, sometimes excited and agitated, so much so as to closely rememble persons under the influence of alcohol. In certain instances there is great difficulty in making the diagnosis from hysteria, early mental disease, or delirium tremens. The author reports cases of this kind that ended in sudden coma and death. He also reports an instance of recovery and one of meningoencephalitis tuberculosa circumscripta, the meningitis *en plaque* of the French writers.

Etiology of Beriberi.—H. Fraser and A. T. Stanton conclude that white polished rice when forming the staple of the diet in man has been shown to cause beriberi. Such white polished rice when fed to fowls produces in them a disease closely analogous to beriberi in man. This reaction has been taken in this, and previous researches, as a test of the beriberi producing power of a given rice when it forms the staple of a diet in man. The addition of rice polishings to a diet of white rice is an effective preventive of the development of polyneuritis in fowls. Rice polishings comprise from 8 to 10 per cent. by weight of the original grain. The substances contained in polishings which are effective in preventing polyneuritis are soluble in 0.3 per cent. hydrochloric acid, and are not precipitated from the solution on the addition of 95 per cent. alcohol in quantity sufficient to make the resulting mixture of proof-spirit strength. These substances comprise 16 per cent., or less, by weight of rice polishings, or 1.6 per cent., or less, by weight of the original unpolished rice grain. The fats which are contained in rice polishings in comparative abundance have been proved of no importance in preventing polyneuritis. Phosphorus compounds equal to 85 per cent. of the total phosphorus content have been proved to be unimportant in preventing polyneuritis.

Primary Carcinoma of the Appendix.—A. M. Kennedy states that the three cases of this condition that he has observed presented features so similar as regards their site of origin that they were of considerable interest, in view of the question of the etiology of tumors in general. In the first case the appendix was divided into two segments, no doubt the result of cicatrization of previous ulceration, and in the sequestrated distal portion the carcinoma was situated. In the second case there was a complete occlusion of the lumen, in all probability due to the same cause, and in this constricted area, and as yet limited to it, the carcinoma was present. In the third case the appendix was also completely occluded in the same way near its tip, and beyond the occlusion, filling up the cavity and replacing the mucous membrane, was the carcinoma. In the first two cases, and probably in the third also, the patient had had more than one attack of ordinary appendicitis; from the histological appearances one can conclude that it is highly probable that in each case a certain amount of localized ulceration of at least the mucous membrane occurred, followed by cicatrization in the process of healing. No doubt this caused considerable disturbance and separation of the epithelial cells of the mucous membrane, and in each of these cases a carcinoma had arisen at the situation of the damage.

A Plea for Graduation in Laryngo-Otology on a Broad Basis. P. W. Williams.
Some Points in the Diagnosis and Localization of Intracranial Tumors. J. S. R. Russell.
The Treatment of Gastric and Duodenal Ulcer. E. C. Hart.
An Unusual Case of Toxic Dematitis, with Remarks on Symmetrical Eruptions. G. Pernet.
Variation Among Bacteria. W. Wilson.
The Therapeutic Advantages of Using Mercury in the Colloid Form. G. A. Stephens.
The Etiology of Iritis. W. W. Beaumont.
The Normal Orthograde Posture. R. H. Scanes-Spicer.

A Broad Basis for Laryngo-Otology.—P. W. Williams states that a sound training in the whole range of general medicine and surgery is the only safe foundation for any special branch. But the tendency is to make another specialty, general surgery, the academic test of fitness in laryngology; medicine, and even a systematic training in laryngo-otology, are made secondary considerations, with a consequent danger of one's becoming too exclusively surgical.

Diagnosis and Localization of Brain Tumors.—J. S. R. Russell states that he has met with cases in which tumor was suspected, and in which general paralysis accounted for the symptoms, but there were other cases in which tumor accounted for what was supposed to be due to general paralysis. In differential diagnosis lumbar puncture and the Wassermann reaction were of value. There are cases in which vascular disease occasions a clinical picture which causes tumor to be suspected, and, although under ordinary circumstances vascular lesions of the brain result in the sudden or rapid appearance of symptoms, exceptions occur in which the progress of symptoms is so slow as to justify the suspicion of tumor. Two classes of cases are met with in this connection, one in which there are general symptoms of intracranial disease without paralysis, and the other in which hemiplegia of slow onset forms part of the clinical picture. A confusion might arise between these cases and aural vertigo, and between the latter affection and intracranial tumor. One may confound the *migraine ophthalmoplégique* with intracranial tumor owing to the oculomotor paralysis which accompanies the headache. Many instances are recalled in which patients had been sent to the hospital for operation for cerebellar tumor, when in reality disseminated sclerosis existed.

Treatment of Gastric and Duodenal Ulcer.—E. C. Hart describes his method of treating these conditions by means of dry protein and normal serum. The avoidance of milk itself as a food, and of soups, broths, etc., and of the custom of drinking with meals, is insisted on. Such veto is based on the impropriety of introducing into a stomach that is often dilated, with a corresponding degree of stasis of gastric contents undergoing fermentation, material that aids stasis and fermentation, such as, in particular, starchy and milky food. The object in the treatment is to give mainly protein food in solid form which will saturate the digestive secretions which are often, in cases of ulcer, not only hyperacid, but hyperpeptic; secondly, to give the food in as small a bulk as possible, consistent with high nutritive value. All these objects can be attained by giving dry meals, mainly of meat, and by never allowing the stomach to go many hours without food. The chief value of the oral administration of a normal serum, whether of man, horse, sheep, or ox, is, in these cases, a local one. Its action in enabling an ulcer to heal is both direct and indirect. Indirectly, it is of value on account of the power possessed by mammalian serums to disinfect an ulcer and to check its advance by virtue of the antiferment activities that all such serums possess. In this way obstruction to healing is to a large extent removed. In addition to the indirect power of normal serums in aiding healing is the marked direct stimulating effect that a serum that is atoxic and sterile has on ulcers. Quite apart, however, from direct stimulation of healing, and from indirectly aiding in cure of an ulcer by inhibition of septic processes, is the action of the serum after absorption in restraining hemorrhage. Previous to 1907 it had been shown by Weil that intravenous injections of normal serums were often of great value in hemophilic and purpuric conditions. With regard to the method of administration, normal serums should in cases of open ulcer never be given to starving patients or on an empty stomach, as troublesome and even serious symptoms may ensue. The author generally prescribes serum in chronic cases of gastric or duodenal ulcer in doses of ten

c.c., three or four times a day, immediately after food, in one-half ounce of cold water. It must be atoxic, as proved by injection into guinea-pigs, and sterile, as shown by the same method or by attempts at culture. It should be stored, if possible, on ice, and is better not preserved by addition even in small quantities of antiseptics, as its antiferment activity is thereby seriously impaired.

Toxic Dermatitis.—G. Pernet reports a case of symmetrical rash which manifested itself in successive outbreaks and which followed the ingestion of bad rabbit. There was a vascular telangiectatic state of the affected areas which followed, showing that the vessels had been smartly attacked in the first place. Other symmetrical lesions of the skin are lupus erythematosus, with its batswing or butterfly patterns; erythema hemorrhagicum faciei; and pellagra.

Variation Among Bacteria.—W. J. Wilson states that the medium in which a bacillus is growing may alter the morphology of the microorganism. Thus the *B. typhosus* has been found to grow out into threads when acted on by various dyes, salts, urea, and by sewage. Similarly, Adami has shown that by the action of a high temperature and the presence of peritoneal fluid the *B. coli communis* assumed a diplococcoid form, and in this case the fermentative characters of the bacillus were also profoundly modified. In most of these cases the organisms soon regained their normal characters when the active agents were removed; in other words, they were examples of fluctuating variations. The author describes a bacillus which was isolated from the urine of a former typhoid carrier and which formed acid, but no gas in glucose media, and which fermented lactose at 22° C., but not at 37° C. In not developing gas in glucose media, but forming some from mannite, it resembles certain colon bacilli of the "anaërogenes" class previously described by the author, and which form connecting links between the *B. coli* and the *B. typhosus* group of microorganisms.

Mercury in the Colloid Form.—G. S. Stephenson states that colloidal mercury is a very powerful antiseptic. A one per cent. solution of colloidal mercury is a greenish brown transparent liquid, without any smell, but with a faint metallic taste. It is non-irritant, non-corrotive, and relatively non-toxic. As a drug it can be used both externally and internally. Externally it has a very good cleansing effect on wounds, when applied in solutions of one-fourth to one-half per cent.

Etiology of Iritis.—H. W. Beaumont believes that it too frequently happens that if one can exclude syphilis and gonorrhea, one may be satisfied, when the patient has indiscriminate pains in indeterminate regions, to call an iritis rheumatic. In many of such cases further investigation might throw doubt upon the diagnosis. Patients cannot be expected to say anything about diseases which they think have no connection with their eye trouble, and so it happens that nothing is mentioned by them about a previous septic throat or pyorrhea alveolaris. Hematemesis and dysentery and dyspepsia are overlooked, and toxemias of all descriptions are forgotten.

The Normal Orthograde Posture.—R. H. Scanes-Spicer states that the normal orthograde posture may be defined as that in which the center of gravity of the head is vertically over the center of the base of support. The vertical plumb-line joining these points bisects the median transverse occipito condyloid axis, and also the intercotyloid axis, passing through also the center of gravity of the mass made up of the trunk and upper limbs. The center of gravity of the head, that of the trunk, and the center of the base of support, are actively distanced as much as possible from each other by fullest possible extension of the vertical axis in which the above points lie with each inspiration until the extension becomes automatic and unconscious. This posture should be the basis of all physical education for the young. It is the ideal one should seek for every child, the one we should endeavor to get stereotyped by growth in form and structure, the one to which such child should automatically return after action or relaxation. The subject trained thus has an easy and graceful carriage, a straight back, well-poised head, a raised, expanded, and mobile thorax well distanced from the pelvis, a flat abdomen, and all the internal organs in constant correct position for best work. The postures permitted and taught by some physical culturists with retracted head, stiff neck, protruded abdomen, hollowed back, and bent knees, do not comply with the author's definition, and are absolute caricatures of the normal erect posture, and directly produce deformity and disease. Moreover, the normal erect posture is the fundamental essential for alt efficient respiration, correct voice production, and speaking. Lastly, the influence of the normal erect posture in the prevention and treatment of disease is of a potency as yet but barely suspected.

Berliner klinische Wochenschrift,

December 1, 1910.

Remarks on Diagnosis and Treatment of Progressive Paralysis.—Bonhoeffer discusses this subject aside from the standpoint of the Wassermann reaction and 606. There is hardly a doubt that paresis is essentially syphilitic in origin, and the belief prevails that the microorganism and its toxins must still be actively present in the paretic. Even the lesions of the disease have long ago been recognized as of a toxic-infectious character, such as is caused by syphilis. Paresis must always be compared with tertiary syphilis, and it is found that the incubation period of the former averages considerably longer than that of the latter. It is evident that something peculiar occurs during this interim. Either the organism or the germ must undergo a change. The paretic does not react at all to Hg and KI. A paretic undergoes remissions, even in the most rapidly progressive cases. These may suggest an unsuccessful attempt of nature to throw off the malady. It has been observed that these remissions follow febrile crises. The lesions of paresis, while such as follow a toxi-infectious process like syphilis, differ radically from lues cerebri. It is upon such grounds that new lines of therapy have sprung up of late, such as the use of tuberculin, nucleinate of soda, etc. Thus far no spirochetes have been found in the lesions of paresis; but these are often absent in undoubted gummata. Kraepelin and others have attempted a study of paresis without the slightest reference to syphilis. They have considered it as an independent world malady, and it has been shown that the incidence of paresis by no means conforms with that of syphilis. It has, of course, long been known that many primitive races which have become saturated with syphilis never develop paresis. Of recent years the clinical diagnosis of paresis has become more difficult. While classical cases are readily recognized, the differentiation of paresis from senile involution is becoming more difficult. Anatomically this difficulty does not exist, and paresis should readily be excluded from the pseudopareses by examinations of the cerebrospinal fluid and blood. While admitting that most patients die before the third year, the author mentions so-called stationary cases with relative recovery. It is difficult to distinguish between cases treated with pyrogenetic media (tuberculin) and those which exhibit spontaneous remissions. In the very earliest stages of paresis one may find lues cerebri associated. It is a question whether the paresis is improved along with the latter under specific measures. The author thinks he has seen three or four complete recoveries from paresis in many years of observation.

Recent Experience with Infantile Paralysis.—Cassirer refers to the isolation of the disease by Heine in 1840

and its subsequent appearance in the various culture countries. Only recently have investigators in different countries shown its communicability and probably contagiousness. We have no knowledge of the virus, save that it can pass through a Berkefeld filter. It is evidently a protozoon and akin to the cause of rabies. We know nothing about the paths of contagion, but disease may appear in household epidemics. It is essentially a disease of the summer months. Like influenza, it may make its début as a respiratory, gastrointestinal, or other local affection, but a meningeal element is usually to be detected. The types of muscular paralysis are amply described by Wickman, who shows that the trunk muscles are very generally involved along with those of the limbs. The condition, strictly speaking, is more than a spinal paralysis, for oftentimes the bulb is involved, and when this occurs the prognosis for life becomes much aggravated. Cases are on record in which the bulb alone and even portions of it were involved. Thus during an epidemic one may see patients with only facial paralysis.

Münchener medizinische Wochenschrift,

December 13, 1910.

Causes of Labor.—Sauerbruch and Heyde devote a short space to this subject, based largely on quasi-experimental findings, to wit, the parabiosis of twin monsters. Pregnancy of one twin gives rise to phenomena in the other twin which are of the character of pregnancy. Two animals of the same species have been so joined artificially as to constitute a single unit. The element of union may vary from a communication between the blood vessels to one between the lymph vessels, or one between the peritoneal sacs. It happened at times that pregnancy in one partner led to death in the other, the pregnant partner remaining immune. These bodies which cause such lethal effects tend to form late in pregnancy and when the fetus or fetuses are well developed. The authors assume that such bodies tend to cause labor pains in the pregnant organism. Failure to develop immunity in the latter may cause toxemia of pregnancy. The authors believe that a study of labor in one parabiotic twin will materially advance our knowledge of pregnancy.

Paget's Disease of the Nipple.—Hirschel reports two cases of this affection and concludes that every instance of eczema of the nipple and areola must be treated most cautiously. In all suspicious cases a trial incision should be made, and if a small cancerous nodule should be found as a cause of the eczema the entire gland should be removed, with a good prospect of radical cure. The author suggests the term cancerous eczema of the breast for all such cases, leaving out Paget's name entirely, for the latter did but note the clinical phenomenon and concerned himself not at all with the histological demonstration. In fact, Paget believed that the cancer arose on an eczematous soil, while our latter teachings show that the cancer comes first and gives rise to the eczema.

Treatment of Constipation by Paraffin Enemata.—Lipowski's first paper on this subject appeared early in 1909. It was recognized that normal man can retain his feces for two or three days without drying, while the constipated man exhibits the peculiarity of unnaturally dry feces from the start. It therefore becomes possible to prevent this drying by enemata. Oil injections for this purpose were recommended by Fleiner in 1893. Its drawbacks are such as may be remedied by paraffin, which must be injected in the fluid state, after which the temperature of the body will serve to maintain it in the liquid form.

Facial Paralysis and Ptomaine Poisoning.—Erben calls attention to various reports in which sardines (for example) have caused facial paralysis in conjunction with symptoms referable to the gastrointestinal tract and even the eye. In fact, facial paralysis seemed to represent a participation of the central nervous system. A general survey of cases of food poisoning appears to show that facial paresis occurs in botulismus—although very rarely—in various kinds of meat and fish poisoning, etc. The peculiar phenomena which have resulted from use of doubtful meat and fish substances are not only numerous but cover the entire field of symptomatology. The whole amounts to a *reductio ad absurdum*. A man develops certain phenomena which are straightway attributed to the injection of preserved foods. There is no direct relationship between cause and effect.

Deutsche medizinische Wochenschrift,

December 15, 1910.

Treatment of Pneumonia.—Hirsch gives a thoroughly up-to-date consideration of this topic, based on the latest scientific accessions. A diagnosis of the type is all important, and this involves the probable outcome of the disease if left to itself. One next has to consider the causal indications, the disease indications, and the symptomatic indications. One must remember that under ordinary circumstances the disease tends to spontaneous recovery. The tendency here is to meddle. Fever need cause no alarm, for in the aged we see death from pneumonia with normal temperatures. These patients are too weak to produce a febrile reaction. Similarly with low temperature we do not need to employ antipyresis. Cases thus let alone give as good results as those treated with aspirin, bathing, etc. Antipyresis of any sort must be used only on the strictest indication and in the absence of the slightest contraindication. Hot derivative baths may be given to children with bronchopneumonia. The author, like many Americans of a past generation, believes firmly in quinine in unusual and complicated cases. This is his first resource when a case appears unusually grave. If circulatory troubles are present and in all alcoholics he would make a special study of digitalis, employing the various concentrated preparations. These he would use hypodermically in emergency cases. In desperate cases he would inject strophanthin into the veins. In heart failure he would use caffein and camphor, but not adrenalin, the action of which is too transitory. In alcoholics he would give throughout either good wine or Stoke's mixture. He has slight belief in the virtues of expectorants, although he makes a possible exception of ammonium chloride. With this might be combined infusum ipecac. which acts upon the peristalsis of the bronchial tubes. For the pains of associated pleuritis, one must use hydrotherapy—never morphia. If delirium tremens develops in potators, we may use in succession veronal, scopolamin, bromides, and opium. Oxygen inhalations can be of little value.

Pregnancy and Tuberculosis.—Hofbauer sums up an article on this threadbare subject as follows: Generative processes exert an unfavorable influence on tuberculosis of the lungs, larynx, skin, bones and joints, in that old latent foci are reactuated. The conditions set up are peculiar, so that one is justified in naming them pregnancy-tuberculosis. They are accounted for in part by the changes taking place in the pregnant organism.

Advances in Gynecology.—Hammerschlag gives a brief résumé of this subject, which really covers but little that is new. He advocates the sterile glove in routine examinations. In the management of leucorrhea he prescribes numerous preparations which act chiefly on the vagina. He warns against gonocidal remedies for the corpus uteri, which should be treated with hot air and baths. The ordinary tampon treatment of the deep vagina and cervix is duly covered, but for metritis proper and annexitis he advocates only massage and the use of an electro-motor. He retains the old belief in laminaria tents to expose the uterine cavity and also advocates the use of the ordinary antidysmenorrheics for painful menstruation.

Book Reviews.

Lippincott's New Medical Dictionary. A Vocabulary of the Terms Used in Medicine and the Allied Sciences, with Their Pronunciation, Etymology, and Signification, Including Much Collateral Information of a Descriptive and Encyclopedic Character. By Henry W. Cattell, A.M. (Laf.), M.D. (U. of P.), Editor of *International Clinics*, Fellow of the College of Physicians of Philadelphia, etc. Freely illustrated with figures in the text. $5.00. Philadelphia and London: J. B. Lippincott Company.

This dictionary is practically a new edition of the dictionary issued some years ago under the editorial supervision of Drs. John Ashhurst, George Piersol, and Joseph P. Remington, though so much amplified and improved as really to constitute a new book. The editor, nevertheless, had the bulk of his work, in the shape of a foundation vocabulary and definition of all the older words, already prepared, so that he was able to devote his attention during the five years the dictionary was in preparation to the definition of the new terms. This work he has done well, for not many of the new words are missing—there are a few, however—and the definitions are usually clear and to the point. The typography and binding are all that could be desired, and the book is not too large (1,108 pages) to be held in the hand while one turns the leaves in his search for a word. Many of the illustrations are good, but a large number are superfluous. There is no value to the user of a medical dictionary in pictures of microscopic sections of aspidium and of licorice root, or of a nettle plant, malva, and podophyllum. A number of portraits of more or less celebrated medical men, dead and living, are interesting, but are of little assistance in clarifying the definitions of any medical words. The selection of pictures is, however, a matter of taste and judgment, and whether there are many or few or what they serve to illustrate adds little to or detracts little from the value of a dictionary; the main thing is to be able to find the word readily and to learn what it means when found. In the latter respect Cattell's—we should say Lippincott's—Dictionary is, as we said before, most satisfactory; in the vexatious obstacles it presents to the ready finding of a word lies its great fault. In an endeavor apparently to save space, the editor has arranged his words largely under the prefixes, yet not consistently so, and the result is confusion—how much confusion may be imagined when, as we are told in the preface (for the editor seems to regard it as a feature), the words trip and tripe are separated by five pages! Trip is grouped with words having the prefix tri-, yet very many words really with this prefix are put by themselves five or six pages away from their immediate alphabetical neighbors. A dictionary of excellence, one which bears abundant evidence of real scholarship on the part of its editor, is thus almost ruined by this provoking disarrangement.

The Proceedings of the Charaka Club, Volume III. $3.00. New York: William Wood & Co., 1910.

It has often been deplored that little or no attention has been directed to the study of the history of medicine in the various medical schools of the English speaking races. While practically every Continental university has a chair devoted to this not only fascinating but important topic, there are but a scanty half dozen such chairs or professorships scattered throughout the length and breadth of England and the United States. Fortunately, however, the true import of historical study is commencing to be more widely appreciated, and in the volume before us we find evidences that here and there are oases in the desert of historical barrenness, and rich ones at that.

This is the third volume of the transactions of the Charaka Club of New York, and contains some of the papers read before this club, members of which are interested in historical and literary subjects germane to medicine. It also contains lists of all of the papers which have been read since the publication of the previous volume, and also an extremely interesting list of the illustrations which have adorned the pages of its three volumes.

In a humorous semi-introduction Dr. Weir Mitchell tells of some humble beginnings of his in the literary field and the recognition, or rather lack of it, that his efforts received. Dr. Pearce Bailey follows with a fascinating account of Flaubert's epilepsy, which he points out was probably not a real organic epilepsy, but had more of the character of hysterical attacks. Dr. Smith Ely Jelliffe gives an account of the life of Franciscus Sylvius, and reproduces a good illustration of the fissure of Sylvius, the only reproduction of this fissure with which we are acquainted appearing in any English article. Under the title, "When Apollo Strikes the Lyre," Dr. Charles L. Dana writes of famous physicians who have cast their work in rhyme and meter, and Dr. Frederic Peterson prints an original dramatic presentation of a borderland case of psychiatry.

These titles only partly indicate the rich store of material found in this most attractive volume, which is a credit to this club, for which we wish a long life and a cordial reception of its transactions by the members of the profession in this country. That an active professional life does not make impossible a dalliance with the Muses is made evident by a perusal of this volume.

Symptomatic and Regional Therapeutics. By George Howard Hoxie, A.M., M.D., Professor of Internal Medicine and Dean of the Clinical Department in the School of Medicine of the University of Kansas; Member of the American Academy of Medicine, American Medical Association, etc.; President, 1909-1910 of Association of American Medical Colleges. With 58 illustrations in text. New York and London: D. Appleton & Company, 1910.

There can be no fear that therapeutic nihilism will ever succeed in planting its red flag upon the ramparts of medicine. The wealth and variety of therapeutic resources at the service of the clinician have until recently been either forgotten or neglected, and their quest practically abandoned in the zeal to discover the sources of disease. The number of excellent works on treatment that have appeared during the past few years sufficiently attest the growing interest and activity in the therapeutic side of medicine. The present work is the latest in this series. Moreover, it contains the material collected for the course in general therapeutics recommended by the Committee on Curriculum of the American Medical Association—a recommendation adopted also by the Curriculum Committee of the Association of American Medical Colleges. More attention is given to the discussion of the principles underlying the various methods of treatment than to an elaboration of the relative merits of the various drugs. The first part of the course deals with symptoms and their relief, and with the relations of symptoms to pathological processes. In the second chapter the treatment of disease is discussed in relation to the therapy of inflammations. The greater part of the book applies these principles to the various disease-entities, thus forming a working manual for the clinician and student. An appendix is devoted to notes and memoranda on the drugs mentioned in the other parts of the book. On the whole this work is an eminently practical exposition of its theme, strictly up to date, and giving a prominent place to physical methods of therapeutics, which have been sadly neglected by the early writers on this subject.

La Vie Sexuelle et ses Lois. Par le Dr. Anton Nyström, de Stockholm. Preface du Dr. A. Marie, Médecin en Chef de l'Asile de Villejuif, Directeur du Laboratoire de Psychologie Pathologique de l'École des Hautes-Études. 6 fr. Paris: Vigot Frères, 1910.

This volume is the translation into French of the well-known work of the Swedish psychologist, whose researches into problems connected with sex have partly tended to lift this subject from the mire in which a prurient literature has all but buried it. The importance of a serious knowledge of sexual psychology is realized when one considers the important rôle played by sexual disturbances in the etiology of the numerous psychoses. As Marie tritely expresses it, a splendid thesis could be written with the title "Amour, crime et folie." One of the most important portions of this book is the author's intensive analysis of modern tendencies toward Malthusianism.

Dawn of the Fourth Era in Surgery, and other short articles previously published. By Robert T. Morris, A.M., M.D., Professor of Surgery in the New York Post-Graduate Medical School and Hospital; Member of the American Medical Association, the New York Academy of Medicine, and other National and Local Societies. Philadelphia and London: W. B. Saunders Company, 1910.

This little volume comprises twelve essays that have already apeared in medical journals and have been widely read. They reveal the originality of the author, and clad in a style scintillating with humor and quaint expressions, they hold the attention of the reader. "The Hand of Iron in the Glove of Rubber" shows some of the disadvantages of the use of rubber gloves, while "The Dawn of the Fourth, or Physiologic Era in Surgery," is an argument for conserving the natural resistance of the patient, and for turning him over to his phagocytes and antibodies in the best possible manner.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

105th *Annual Meeting, Held November* 28, 1910.

The President, Dr. John E. Weeks, in the Chair.

Executive Session.—Reports were read of the Comitia Minora, the Treasurer, the Censors, the Counsel, Standing Committees, Special Committees, etc.

Proposed Amendments to the By-Laws.—After considerable discussion, both of these amendments were lost.

"Optometry" Course at Columbia University.—Dr. Eden V. Delphey introduced a resolution censuring Columbia University for instituting a course in optometry whereby incompetents would be turned out to menace the eyesight of the community. After much discussion it was moved and carried that the President should appoint a Committee of Five, the President and Dr. Delphey to be members, to consider this matter and report back to the Society at its next meeting.

Listing Physicians in Directories.—Dr. Eden V. Delphey offered a resolution, which was seconded and unanimously passed, that in any directory or list, other than a medical one, the use of more prominent type for one name than for another, or the insertion of any data except the name, address, and telephone number unfavorably affects the character, dignity, and interests of the medical profession.

Election of Officers.—*President,* Dr. James K. Mc Kernon; *First Vice-President,* Dr. Charles Gilmore Kerley; *Second Vice-President,* Dr. T. Passmore Berens; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson; *Censors* (to serve two years), Drs. John E. Weeks, John J. McPhee, and Howard Lilienthal. The following were elected delegates to the Medical Society of the State of New York, to serve two years: Drs. H. Seymour Houghton, Floyd M. Crandall, Ward B. Hoag, E. Eliot Harris, Charles H. Richardson, Walter Lester Carr, Henry M. Silver, J. Milton Mabbott, Egbert Lefevre, John E. Weeks, Irving D. Steinhardt, Rosalie S. Morton, Angenette Parry, Mary Sutton Macy, Walter W. Strang, Mathias L. Foster, and Richard Stein. The following were elected delegates to the Medical Society of the State of New York, to serve one year: Drs. Frank S. Fielder, Louis Faugères Bishop, and Ralph Waldo.

The Diagnosis of Surgical Diseases of the Stomach and Biliary Passages.—Dr. Charles N. Dowd read this paper.

Some Remarks on the Surgery of the Biliary Passages.—Dr. Alexander B. Johnson read this paper. To be published later.

Hematogenous Infections of the Kidneys.—Dr. George Emerson Brewer called attention to some conditions which somewhat closely simulated intraabdominal infections and which not infrequently led to error in diagnosis. He detailed one case of acute hematogenous infection of one kidney.

Dr. Charles H. Peck called attention to one condition met with, *i.e.* acute perforation of the stomach or duodenum, in which the advances in the treatment had been very striking. He had, as a hospital interne, seen such cases recognized, but allowed to die without operation, a few years ago, while today they were invariably operated upon and with successful results. He had personally had twelve cases of acute perforation of the stomach or duodenum resulting from ulcers thereof, with three deaths, all of the cases operated upon within twenty-four hours having recovered. Brilliant results had been obtained especially in the chronic duodenal ulcers, and great credit has been due for work in this line to the efforts of such men as Mayo of this country and of Moynihan abroad. Duodenal ulcers and pancreatitis were much more commonly recognized to-day than a few years ago. Dr. Peck called attention to one comparatively rare acute abdominal condition, acute hepatitis; he reported such a case five years ago, a case of acute inflammation of the liver, which was apparently an affection of the parenchyma rather than of the bile ducts. Recently he had had two other cases. This added one more condition to be considered among the acute inflammatory conditions of the upper abdomen. In his third case the cultures from the portal circulation revealed the *Staphylococcus aureus;* there was a degeneration of the liver cells most marked at the periphery of the lobules. The condition he described was only occasionally met with; he believed it to be due to a toxemia or infection, the poison being carried to the liver through the portal circulation.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held November 21, 1910.

The President, Dr. Reynold Webb Wilcox, in the Chair

Tumors of the Female Breast.—Dr. George N. Balleray of Paterson, N. J., said that for twenty years he practiced general surgery, and he thought it safe to say that during that time at least 50 per cent. of all cases of this character occurring in Northern New Jersey fell into his hands, either in hospital or private practice. Later, when he decided to confine his practice to abdominal and pelvic surgery and gynecology, he made an arrangement with his colleagues at St. Joseph's Hospital, Paterson, by which all female patients suffering from mammary tumor should be referred to his service. It could be seen, therefore, that this was a subject in which he was deeply interested. The importance of early and correct diagnosis and of prompt and efficient treatment in this class of cases could not be overestimated. In his early experience it was not uncommon to have referred to him patients with cancer of the breast in such an advanced stage that operation of any kind was out of the question. Now, however, there was a change, and not infrequently unnecessary and unjustifiable mutilating operations were performed for simple benign growths, which an intelligent surgeon would have removed without inflicting any serious injury upon the breast itself. The etiology of mammary neoplasms was obscure, and it was wiser for us to acknowledge our ignorance of the cause than to attribute them to influences which probably have nothing to do with their origin. He doubted whether traumatisms of the breast predisposed to cancer, for it was certainly true that in a large proportion of cases no history of traumatism could be traced. He did believe, however, that heredity plays an important part in the etiology of cancer. He cited cases tending to establish such relationship, and expressed the opinion that it was improbable that these were simply coincidences. Tumors of the female breast being of two general classes, benign and malignant, it was evident that the ability to distinguish between these two constituted the key to their intelligent and successful treatment. In a general way it might be said that all mammary tumors appearing in women younger than thirty-five were innocent, while those appearing at a later age were almost always malignant. To this rule there were few exceptions. He had seen cancer of the uterus in a patient of twenty-eight, but did not recall a single instance in which carcinoma of the breast appeared before the thirty-fifth year. Sarcoma was the form of malignant disease most frequently met with in young subjects. The benign growths which had been observed were lipoma, enchondroma,

osteoma, angioma, fibroma, adenoma, cyst, cystofibroma, and cystoadenoma. In addition, there was a variety of tumor, occuring principally in single women and childless wives, which generally enlarged at each menstrual period, and also became sensitive at this time. They might last for months, or even years, but disappeared spontaneously, unless the patient should consult some unwisely meddlesome practitioner. The frequency and nature of this class of tumors were not sufficiently appreciated by the profession; hence errors in diagnosis and treatment were common. They were due, in Dr. Ballcray's opinion, to duct obstruction, with localized inflammation; so that when this subsided the tumor disappeared. They should not be confounded with the "phantom tumor" and "hysterical breast" of some authors.

In diagnosis, the *tactus eruditus* was of great importance. Cysts with thick, dense walls felt much like solid growths, and, as they often appeared at about the age of forty, might easily be mistaken for cancer. When such a cyst was gently pressed against the chest-wall by the hand laid flat upon the breast, a feeling of resiliency might be noted, and sometimes deep pressure with the pulp of the forefinger over the center of the tumor elicited a sense of fluctuation. As a rule, the nipple was not retracted, and pain in the breast was rare. These cysts were often multiple, and this characteristic assisted the diagnosis, as malignant growths were almost invariably single. He had once seen the breast removed in a case of simple cyst, the patient being over forty. Previously an exploratory incision, penetrating the tumor to the extent of about an inch, had been made, and the appearance of the tissues was indicative of malignancy. After the operation, however, it was found on examination that the tumor was a simple cyst with very thick and dense walls; so that if the exploratory incision had extended a little deeper the true character of the tumor would have been revealed. Microscopic examination of a frozen section of the cyst-wall when the incision was made would probably have established the diagnosis, but, unfortunately, an expert microscopist is not always at the surgeon's elbow to help him when in perplexity. Chronic abscess had repeatedly been mistaken for cancer, and without an exploratory section a positive diagnosis was sometimes impossible. On two occasions he personally had amputated the breast for supposed carcinoma in patients suffering from this condition; but these cases occurred before he began to make exploratory incision a preliminary step in almost all operations for mammary tumor. In the examination of the breast a careful exploration of the axilla should never be omitted. Lipoma, angioma, osteoma, and enchonchroma were all extremely rare.

In all benign tumors the prognosis was good if the patient was treated intelligently, while in malignant ones many circumstances tended to modify the prognosis. In carcinoma, the older the patient at the time of the first appearance of the growth, and the slower the progress of the disease prior to operation, the better the chance for non-recurrence for a long period. Early diagnosis and radical operation might result in a very long immunity from recurrence. The speaker took up the question whether cancer of the breast was ever cured by operation, and stated that at the present time he had patients alive and well twenty-five, twenty and fifteen years after operation. Most surgeons would say that they were really cured, but he was not willing to go as far as that. When a patient was pronounced cured simply because she had had no recurrence for a matter of three years, this assertion, in his opinion, was a little premature. Twenty years ago he could have presented an imposing array of such cases, but, for aught he knew to the contrary, many of these patients might in the meantime have died from a recurrence. Every surgeon of large experience knew how difficult it was to trace postoperative cases for any great length of time.

Surgical treatment was the only kind of treatment applicable to mammary tumors. Benign tumors should be extirpated without materially injuring the breast; but to this rule there were exceptions, and he had several times removed the breast as an elective operation for multiple cysts with thickened walls. Simple cysts might be cured by incision and drainage with iodoform gauze, though it was sometimes better to dissect out the cyst, or to curette its cavity, before inserting the gauze drain. A mistake often made was that of attempting to enucleate solid growths, such as filromata and adenomata, through an incision not extending deeply enough; consequently there was bruising and tearing of the surrounding tissues which might result in considerable harm. The secret of success he believed lay in efficient drainage of the deep cavity apt to be left after removal when the growth was of some size. Single cysts which had thickened walls with shaggy villosities, resembling papillomata, proejcting into this interior demanded amputation of the breast, as in the case of multiple cysts with thickened and indurated walls. All malignant growths called for radical operation. In the few cases of sarcoma of the breast in which Dr. Ballcray had operated the disease returned in about a year and resulted fatally in a few months. On the other hand, in carcinoma his results had been so good that he believed his method of operating entitled to serious consideration. This method consisted in removing the breast with as much skin as could be taken away consistently with leaving all that was required to bring the edges of the wound in apposition. Whenever there was the slightest doubt about the diagnosis the operation was begun as an exploratory incision, radiating from the nipple and extending deeply into the substance of the tumor. The breast was removed by means of an elliptical incision, beginning at the anterior border of the axilla and extending to or near the sternum; the lower part of the incision always being made first. The layer of fat having been reached, the knife was held in a slanting position and the fat cut through in a way to undermine slightly the edge of the skin incision, by which means a larger area of fat than of skin was removed from the breast. The incision was then extended through the pectoral fascia, which was dissected away, and skin, fat, breast, and fascia were removed in one piece. The flaps above and below were dissected back to the extent of an inch or more, care being taken not to come so near the skin as to impair its vitality and thus lead to subsequent sloughing. The axilla was next opened by a liberal incision, and all the fat and glands removed by careful dissection. This "clearing of the axilla" should be practised in every case of cancer of the breast, whether diseased glands could be felt or not, unless the condition of the patient was such that the continuation of the anesthesia and the operation would be too hazardous. The removal of the flaps enabled one to bring the edges of the wound in apposition, or nearly so. The wound was closed with silkworm gut sutures and two rubber drainage tubes were generally employed, one in the axilla and the other about the center of the wound made for the removal of the breast. These were brought out through a stab wound, and not through the original incision. Iodoform gauze was placed over the wound, and the dressing completed with sterile gauze, absorbent cotton, and a roller bandage. The immediate and ultimate results of this method had convinced Dr. Ballcray that it had many advantages over Halsted's operation in cases in which the pectoral muscles and subjacent glands were not affected and the skin was not very extensively involved. He claimed that the Halsted procedure should be reserved for cases of the latter character, holding that with surgeons less skillful than Halsted, and in old and feeble patients, the mortality from this operation outweighed its prospective benefits.

Dr. Samuel Lloyd said that he agreed with the reader of the paper, to some extent, as to the occurrence of benign tumors in younger women. It was now recognized, however, that carcinoma may appear at any age. On one occasion more than twenty-five years ago, when he was present at the clinic of the late Dr. Bull at the New York Hospital, he was invited to examine a young woman of twenty-six with a tumor of the breast. It was the youngest case of the kind he had ever seen, but the growth had all the characteristics of malignant disease, and when he was asked his opinion as to the treatment required he had expressed the sentiment that all tumors of the female breast should be removed. This happened to exactly correspond with Dr. Bull's own views, and the latter repeated it with great emphasis to the class. A benign tumor of the breast, Dr. Lloyd went on to say, was a constant source of irritation, and if the patient had any tendency to the development of cancer such a growth would almost certainly become malignant if allowed to remain. In doubtful cases of tumor it was important that a section should be made through the center of the growth, for diagnostic purposes, as an incision less deep than this was apt to be misleading. In advocating removal he did not mean to say that the patient should always be subjected to a complete operation, such as the Halsted, but it was essential that the entire growth should be extirpated. Traumatism, in his opinion, was a factor in the causation of cancer only to a limited extent. He could not agree with Dr. Balleray in regard to the matter of heredity. Heredity was no more a cause in this affection than in the case of tuberculosis or any other infective disease. The soil was there, and in these patients the system was ready for the infection if the opportunity offered for its development.

Dr. J. Herman Branth said that in the last century it was a great surprise to Dr. Rudinski of Iowa when, after applying the *x*-ray in a case of mammary cancer where he knew of nothing else to do, he found that a cure resulted. The whole medical profession then thought that now at last there was a remedy for cancer. There were many enthusiasts, and numbers of physicians acquired an *x*-ray apparatus as a necessary outfit in their armamentarium. This form of treatment was now resorted to for almost every imaginable ailment. After years of practical experience, however, it was found that there was a limit to the efficiency of the *x*-ray. In January, 1904, Dr. Branth had read a paper before this association in which he stated that he did not observe good results from *x*-rays in deep-seated cancers. There might, and often did, follow their use an arrest in the progress of the disease, but he had never seen a complete disappearance of a growth of this kind. The cancer, at any time in the future, might break out with more or less violence. The opinion which he had expressed at that time was now fully confirmed. He had not observed a cancer of the breast get entirely well under *x*-ray treatment. Dr. J. A. Reviere of Paris and Dr. Keating Hart, with whom he had a controversy as to the matter of priority in the use of the method, both spoke in the highest terms of the efficacy of high frequency currents, claiming many recoveries and a right to banish the knife. The speaker said he was one of the oldest workers with the *x*-ray in his country. He had passed through severe burns from too much exposure to the action of the rays, and thought he could claim mastership in this line of work; yet he was free to confess that he had failed to achieve such results with either *x*-rays or high frequency currents in mammary or any deep-seated cancer. It should be borne in mind, however, that superficial cancers were quite amenable to *x*-ray treatment. The high frequency spark on the open wound after operative removal of the tumor was first employed in Heidelberg, and laudatory reports of its use had been published. This treatment was very painful, and could be given only under narcosis. It was his belief, based on personal experience, that nothing better than the knife had yet been found for cancer of the breast. The great trouble was that many physicians hesitated to use it early, while most patients were only too glad of delay and were willing to accept any substitute. When any tumor appeared in the breast it ought at once to be completely extirpated with the knife (cutting wide of it), for if allowed to remain it would almost surely become malignant in time. Such an operation at this period was not a serious one, and great hope for the nonrecurrence of the growth could be entertained. When the tumor had developed into an ulcerative one, with infiltrations and infected glands in the neighborhood, recurrence, notwithstanding a wide cut into apparently healthy tissue, was the rule and nonrecurrence the exception. It would seem from this that cancer in the beginning is a local disorder, and in all cases it behooved us to warn our patients against the dangers of delay. Dr. Branth believed that, after excision, *x*-rays and the high frequency current were helpful measures. As a local application to destroy odor in cancerous growths fusel oil, 3 to 10 drops, was very efficient.

Dr. Carl Beck agreed with Dr. Branth that the *x*-ray should never be employed instead of the knife, but was of service in the postoperative treatment.

Dr. Balleray, in closing, said he entirely agreed with Dr. Lloyd as to the importance of deep exploratory incision for diagnostic purposes. In the case of benign tumors the operation of removal was not serious, and with simple adenoma or fibroma enucleation was all that was required. There was never any recurrence of these benign growths. Carcinoma he believed to be exceedingly rare in young women, while sarcoma was more common in the young.

The Operative Treatment of Fractures.—Dr. John B. Walker said that recent records showed that 75 per cent. of suits for damages against the medical profession were surgical suits, and that of those 65 per cent. were on account of defects following fractures. Yet during the past two decades surgeons had for the most part been concentrating their attention upon abdominal lesions, while the treatment of fractures, which were of most frequent occurrence, had been somewhat neglected. And this in the face of the fact that since the *x*-rays had enabled one to see and photograph the broken bones, greater skill than was formerly the case was now demanded in the treatment of fractures. In the past results in ordinary thigh fractures had been accepted as satisfactory which were now considered most unsatisfactory. A number of years ago Lane, after a study of the statistics of various London hospitals, found that a very large number of patients who had suffered from fractures of the lower extremity had their earning capacity greatly lessened on account of faulty union, which manifested itself by pain and discomfort. Numerous other records also indicated that the results of conservative treatment in thigh fractures have not, as a rule, conformed to the high ideals which govern every modern surgical undertaking. It was customary for the larger New York hospitals to transfer the fracture cases to Bellevue Hospital, in order to keep their beds free for patients who might require laparotomies. Consequently, a large number of fractures failed to receive appropriate treatment within the first forty-eight or seventy-two hours. During the past twenty months there were admitted to a surgical division of Bellevue one hundred patients suffering from fracture of the femur. A large number of these were received from other hospitals, where a temporary splint had been applied. On admission, the cases were usually dressed with a long side splint. Within forty-eight hours this was generally removed and a Buck's extension apparatus applied. After traction had been employed for two to three weeks, or until it was impossible to overcome any further shortening, a plaster spica was applied and continued for several weeks until the patient was allowed to

be up and about on crutches. Having given the statistics of these cases as to shortening, on admission and at the time of discharge, the speaker said it seemed quite clear, and very important, that there should be developed some adequate improvement in the method of treatment for these cases of fracture of the femur. More than fifteen years ago Lane of London, after analyzing his extensive investigation on the end-results of fractures, concluded that in order to secure complete restoration of function it would be necessary to secure accurate apposition and alignment, and that this could best be obtained by operation. He accordingly began to operate upon recent fractures, and his brilliant results had stimulated many surgeons to undertake similar methods. Each succeeding year there had been reported an increasing number of successful operations, and the renewed prominence given to this important branch of surgery warranted an extended examination of the situation from all points of view, in consideration of the widely divergent opinions held by many eminent surgeons. Dr. Walker gave the details of a number of his cases, and in connection with the paper presented six of the patients upon whom he had operated. The first of these was a boy of eight years who had had a fracture of the femur which could not be reduced by means of extension. He was operated upon in June last, and a Lane plate inserted, and there had been a properly satisfactory result, without any shortening. The second patient was a male child sixteen months old who at birth had a fracture of the upper third of the femur, and here also there had been a perfect recovery. The third was a woman of 45 who had had a fracture of the upper third of the femur. She now walked without difficulty, and there was practically no shortening. The fourth patient was a woman of 28 who had had a fracture of the neck of the femur. Two years after the accident there still remained 1¾ inches shortening. At the operation it was found that the femoral neck projected about half an inch above the upper rim of the acetabulum, and the fracture had occurred roughly transversely through the femoral neck; the proximal fragment, which practically filled the acetabular cavity, consisting of the upper third of the femoral head. Considerable callus surrounding the fragments was removed, and the surfaces freshened, and it was also necessary to remove a portion of the acetabular rim in order to bring the fragments into apposition. By traction and abduction the freshened fragments were brought together, with great difficulty, and a steel drill was passed through the great trochanter (the neck) and the head and into the wall of the acetabulum, thus spiking the fragments together. The wound was closed with a small rubber tissue drain projecting, and a plaster spica applied from the lower border of the ribs to the toes. The patient was confined to bed for eight weeks. Four weeks later a Thomas hip splint was applied, and she was permitted to go about on crutches. Five months after the operation the drill, which was loose, was easily removed by small forceps. The hip splint was discontinued at the end of one year. She now walks without a cane and is free from pain. There is about three-quarters inch shortening, which is compensated for by her shoe. The fifth patient was a woman of 30 who had fracture of the tibia and fibula, at the lower third. At the end of six weeks' treatment with plaster of paris it was found there was no union. A plaster bandage was again applied, but after two weeks more there was still no union. She was then operated upon, and it was then found that the reason for the nonunion was the presence of a piece of periosteum between the fragments of both bones. A steel plate was applied and complete recovery resulted, without shortening. The last patient shown was a boy who had had a fracture of the lower third of the humerus. Delayed union in fractures was largely due to faulty adjustment, and the rapidity and completeness of cure were proportional to the accuracy of reduction and the retention of the fragments. It was most important to secure correct alignment, as this prevented a harmful deflection of the body weight and the pressure arthritis so ably demonstrated by Mr. Lane. A radiograph was important within two weeks after the reduction. It was necessary to interfere later far more often for bad results of treatment than for errors in diagnosis. Anesthesia should be much more frequently employed in the reduction of fractures, and always in the treatment of those involving joints. Operation should be resorted to as soon after the injury as it had been determined that reposition was possible by no other method. If a fracture were considered, as a wound, the sooner the wound surfaces were brought together and retained in apposition the less would be the swelling and the more perfect the healing. The skin, which should be rendered absolutely clean, should be excluded from the wound and covered with gauze. The vessels were obliterated by means of strong compression forceps, so that ligatures were not required. For holding the fragments in place wire was unsatisfactory. Wood screws were the most satisfactory. The operative method was indicated, not only for the immediate accurate reduction of displaced fragments of long bones whenever it is impossible to correct the deformity without operation, but also for the removal of soft parts between the fragments, which is the most frequent cause of nonunion. In operating it was necessary that an asepsis must be observed far superior to that requisite for other operations, because a considerable quantity of metal is left in the wound. In conclusion Dr. Walker said that fractures should be carefully *x*-rayed in planes crossing each other at right angles, so that any displacement should not escape observation. A surgeon who did not insist on an efficient radiograph being taken at the earliest moment in any suspicious case of injury rendered himself liable to much criticism and financial loss in the future.

A Few Neglected Points Concerning the Treatment of Fractures, with Special Reference to Those of the Leg.—Dr. Carl Beck said that fracture of the leg, being the second most frequent form of fracture, deserves much more attention than it usually receives. Especially was the fibula ignored because it was looked upon more as an appendage than one of the sustaining elements of the leg. The contention of P. von Brems, that the line of fracture in those injuries is generally oblique, and that a considerable proportion come under the heading of the "torsion type," was very much doubted until it was corroborated by the *x*-rays. Even now, however, some surgeons declined to use the rays, on the ground that, on account of the superficial location of the bones, a positive diagnosis could readily be made by means of palpation. If the direct violence of the injury were great, the tibia would break, while the fibula might assume a bent position without breaking. This was shown in the radiogram of the leg of a nine-year-old boy. Within the area of the most extensive bending a destruction of osseous molecules always took place. This was not recognizable macroscopically, but could be observed in the stronger shading of the Röntgen plate. In such cases if the fracture of the tibia were not reduced early, considerable reaction would result in this fibular area, and examinations by the *x*-rays several weeks later had frequently revealed signs of inflammatory atrophy. Cross-fractures were usually dentated, which favored their steadying after reposition, but in most cases both bones were broken, and the direction of the line of cleavage was an oblique one. The formation of the lines might also be different. This was illustrated in a radiograph showing the triangular form of the tibial fragment and the marked overriding of the fibular fragment. The shortening of the leg was in proportion to the extent of this overriding. Having referred to some special

varieties of leg fracture and to the efficiency of the circular plaster of paris dressing, the speaker said that in cases of the usual oblique fracture simple retention of the fragments by dressing alone was not sufficient. The tendency to slipping was best overcome by forced extension under anesthesia by the method devised by Gurdon Buck and improved upon by Bardenheuer. A radiograph taken previously would indicate the direction in which the efforts at reduction are to be carried out. If the knee and ankle were immobilized in the hyperextended position a sufficient amount of extension would persist until the dressing had hardened, and no disturbance was to be expected after the muscular contraction had disappeared. The best proof of a successful reduction was the Röntgen plate taken through the cast. There was no danger of pathological pressure as long as the osseous fragments were kept immobilized. The danger lay in insufficient reduction, which meant continued irritation, and under these circumstances he had frequently observed gangrene beneath the best-padded splints and dressings. Care should be taken not to apply the dressing too tightly. The force in making extension should be exerted exclusively by the assistant, while the surgeon devoted his attention to the directing and molding. The marked tendency of the fibular fragment to lean against the tibial portion might be combated by elastic interposition, such as Dr. Beck had originally advised in the lateral displacements of metacarpal fracture. A rubber drainage-tube about the size and thickness of a man's finger was placed above and along the interosseous space, and retained in position by adhesive strips. In the beginning, elevation of the leg on a well-padded underlayer was recommended. For the period of observation and after-treatment residence in a hospital was preferable for the patient. If by any chance signs of arrested circulataion should manifest themselves the dressing should be at once changed. If there was no reaction the dressing, which would have become too loose by the resumption by the soft tissue of their normal contours, should be removed in about a week, and a tighter dressing substituted. If the fragments were entangled in such a manner that exposure by blunt means was impossible, a chisel operation became necessary. By using the chisel as a lever, and working it up and down, removing loose and penetrating splinters, the area was freely exposed and the separated ends were approximated by means of flexible bronze wire. If the fragments could not be kept in situ in this way, proper alignment might be preserved by shaping one of the ends triangularly and making a shallow groove, in which it might fit, in the other. Under such circumstances the wiring of the fibula might be dispensed with. In the spiral type of fracture, if there was difficulty in adjusting the fragments, it might be necessary to flatten off the triangular ends, thus creating two smooth surfaces which fitted exactly and would prevent gliding when they were wired together. The question of coaptation was of the same moment in bone surgery as in accurate union of the soft tissues. For the most part the principles governing the operation were identical with those concerned in the technique of plastic operations. For some years Dr. Beck has been accustomed to paint the integument over the field of operation with a solution of tincture of iodine. For each of the bones a separate longitudinal incision is made, and the fragments lifted from their beds. While the ends of the fragments are grasped with strong forceps a hole is drilled through the bone extremity about one inch from its distal margin. The bronze wire is passed through the perforations and at first knotted loosely. The bones are then pushed back into their normal position and the wire knotted tightly. The long wire ends, left protruding from the wound, are wrapped about with xeroform gauze, and in from four to six weeks are extracted. Fascia and periosteum may be united with fine catgut. In old and badly united fractures the principles of procedure remain the same, but the fragments must first be rendered movable by means of the chisel. The speaker then said that special attention must be paid to those fractures situated in close proximity to the joints, on account of the question as to function involved. In open fractures he carried out the principles previously laid down. First of all he studied the Röntgen plate to find out whether he could hope to restore individual bone fragments to their normal positions and fasten them there, or whether it would be better to remove them and resort to drainage. In septic infectious a moist bichloride dressing was first applied, and immobilization maintained by means of wire splints. After the swelling had disappeared dry treatment through a fenestrated plaster dressing might be more desirable. Two illustrative cases were cited. All methods had their disadvantages, he said in closing, but wiring seemed to him to give the best results. In connection with the paper Dr. Beck presented a boy who had had a supracondylar fracture of the right arm. In this case he had expected to have to use wiring, but in cutting down upon the seat of injury he found it possible to replace the fragments and keep them in position without resorting to this.

Dr. Carl E. Pfister reported two cases. The first was a compound fracture of the tibia and fibula. At first he thought amputation would be necessary, but as the *x*-ray showed something lodged between the fragments he decided to cut down on the seat of fracture before resorting to this. He found portions of periosteum between the fragments, and, having removed these, he was able to reduce the fracture and get a good result. The second case was one of fracture of the elbow in a boy, and here also the *x*-ray afforded valuable assistance. It would be very satisfactory, he thought, if all such cases could be treated in hospitals, but as this was impossible a portable *x*-ray apparatus was much to be desired.

Dr. Kingman B. Page said that traction, as by Buck's extension, was a matter which had been too much neglected by the average surgeon. The use of plaster dressings, without this, accounted largely for the shortening and other defective results so often observed. Great credit was due to Dr. Walker, he thought, for the admirable results he had reported in fractures of the femur, high up.

Dr. Benjamin T. Tilton said that fractures of the lower leg had certain peculiarities which rendered them of special clinical interest and which often presented certain difficulties in securing a good result. In the tibia incomplete fractures are not at all uncommon in adults as well as children. Such fractures may easily be overlooked, as most of the symptoms of fracture are absent. Linear tenderness and a slight "rocking" of the fragments may be all that points to fracture. The *x*-ray is of great assistance in these cases. Another peculiarity of fracture of the tibia is the tendency to pseudoarthrosis, and this is most likely to occur where there is overriding of the fragments, as in the oblique and spiral fractures which are so common here. Neuralgia is also a frequent symptom following badly united fractures in this region. Hence, it is desirable to secure and maintain a complete reduction. For this purpose Buck's extension, modified for this region, may be advantageously used in the cases where overriding occurs easily. It is very exceptional that open operation is required to maintain approximation, and operative procedure should be limited to cases of badly united fragments and of interposed soft parts. This is not the case, however, in fractures near joints, where it may be difficult or impossible to maintain reduction. Fractures of the upper part of the shaft of the

femur are good examples of this. The *x*-ray is, of course, very valuable in the diagnosis and in securing a satisfactory reduction, but it is often misleading as regards the prognosis. Many fractures of the leg unite with perfect function, and yet the *x*-ray picture shows far from a satisfactory alignment of the fragments. This fact has to be taken into consideration in lawsuits, especially against a physician treating a fracture.

Dr. Jacob Heckmann said he had assisted Dr. Beck in many of his fracture cases. In the neighborhood of joints he thought it inadvisable to make use of wire sutures or any other foreign body.

Dr. William Darrach said the open treatment of fractures had recently attracted much attention. In the 300 cases of Flint silver wire was first employed to maintain apposition of the fragments, next bronze wire, then phosphor-bronze wire, and finally the metallic plaster. The latter was made of steel, as used by Lane, or of sufficiently heavy aluminum. The question which now presented itself was, shall we treat fractures by the closed or the open method? Personally, he believed that in every instance where the closed method could be employed satisfactorily it should be used, but that in all cases where we cannot secure and retain satisfactory reduction the open method should be resorted to. Satisfactory reduction did not necessarily mean perfect reduction. Often there was interference with function, and to determine in any instance whether this was likely to occur required an immense amount of study of cases. For operative work the ideal time was immediately after the injury.

Dr. Branth said that the Lane method of treating fractures was one of the greatest advances ever made in bone surgery. In this the surgeon cuts down to the seat of fracture, removes bloodclots and loose spiculæ of bone, and dislodges tendons and muscular tissue when these have become interposed between the fragments, placing them in proper position for future normal function. He then brings the fragment ends into accurate apposition, a matter by no means difficult, since the muscles are relaxed by anesthesia and the parts are in view. In all fractures, whether transverse or oblique, there is a serrated condition of the fracture surfaces, and this, by the interlocking, assists in maintaining correct apposition. The periosteum is also drawn as far as possible over the fracture. The steel plate is laid on parallel with the shaft of the bone, a hole drilled in one end of the fractured bone, and a screw inserted to hold that extremity of the plate in place. Then the plate is adjusted so as to overlap the end of the other fragment, and the limb is brought into normal position and held steady by assistants. A hole is drilled for the second screw and the screw brought home, after which the soft parts are carefully adjusted, perhaps with the aid of sutures. All clots are removed, the wound is closed aseptically and covered with gauze, and the limb is bandaged with plaster rolls. It is remarkable what firmness is secured by by such a simple apparatus. By the treatment described the fractured surfaces are brought into, and maintained in, accurate apposition, and nature has but little to do in establishing repair. There is less spasm of the muscles because less irritation, the parts being all in place, and there is little opportunity for shortening. Dr. Branth was the guest of Mr. Lane in 1905 and again in 1906, and on one occasion the London surgeon showed him a patient who had been brought to Guy's Hospital suffering from fracture of the femur, near the upper third, and also from delirium tremens. This man was walking in the wards with a cane five weeks after a Lane operation. His (Dr. Branth's) doubts as to the correctness of the statement made, in view of the fact that fracture of the thigh complicated by delirium tremens generally means a fatal issue, were dispelled by the hospital records and by *x*-ray examination showing the plate in position. He made three examinations personally. Mr. Lane uses a sterilized steel plate, two to three inches long, and wood screws. The latter have a long neck, and the screw end may reach through the bone-wall into the marrow, in which case the neck of the screw would act like a nail or peg. Such a screw is liable to slip and thus spoil the result. Dr. Branth has seen such a case, verifying the condition by measurement and *x*-ray examination. He therefore suggests the employment of the machine screw, which has a thread extending quite up to the head, as such a screw will hold more firmly in the bone than the wood screw. One might ask, he went on to say, what becomes of the metal plate? It remains where fixed, and callus will surround it, making the union only the firmer. Applied under proper conditions it does not cause any trouble. Should an abscess and sinus form, and the plate be cast off, it is owing to a defect in asepsis or because some dead débris was left by the operator. The Lane method of treating fractures would therefore appear to be ideal. Of course, low vitality, as produced by preexisting conditions such as diabetes or Bright's disease, is a factor to be considered in the prospect of recovery.

Dr. Walker, in closing, said that after his operations there had been no case in which any untoward result occurred or in which it was necessary to remove the plate; nor had any of his plates ever come out.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

334th Regular Meeting, Held November 4, 1910.

Dr. Robert Abbe, President pro Tem.

Youthful Diabetes with Results of Treatment.—Dr. L. A. Conner said that as the belief was so general that diabetes in a child was always a severe and progressive disease, which showed little or no response to treatment and usually ran a rapidly fatal course, he presented this patient to show that the prognosis in children was not always so gloomy, if they could be placed under favorable conditions. The patient, a girl of 12 years, had been somewhat feeble-minded since birth, but had always been well except for an attack of measles when two years old, and of scarlet fever when six. Her present trouble began two months before her admission to the New York Hospital on September 28, 1910. During these two months there had been increasing weakness, rapid loss of weight, increased appetite and thirst, polyuria, headache, and vague abdominal pains. She had been treated in the Out Patient Department, but unsatisfactorily because of difficulty in controlling her diet. On admission the child was emaciated, weak, and listless. Examination of the viscera was negative. She was put on a strict diabetic diet plus 150 grams of white bread, and on this diet she excreted in the first twenty-four hours 3,500 c.c. of urine containing 278 grams of sugar. Acetone reaction was positive. At the end of six days the patient was on a strict diet without any bread or other starch, and the twenty-four hours' urine contained 70 grams of sugar. Although the urine gave a marked reaction for both acetone and diacetic acid the child's general condition seemed better. It was decided to continue the strict diet. After four days of this the acetone and diacetic acid had grown less, but the quantity of sugar excreted was almost unchanged. During the next ten days the diet was changed in various ways. Meat was restricted. "Vegetable days" were interspersed between days when only oatmeal and cream were given, with the result that on the twenty-first day of treatment the patient was free of sugar, the urine was normal in quantity, and gave no reaction for diacetic acid and only a very slight one for acetone. In the meantime the child

had gained steadily in strength and spirits, and had begun to gain in weight. From that time on, on a strict diet, the child remained practically sugar free, on two or three occasions only showing just a trace. Upon the addition of even 25 grams of bread, however, the urine would show a small amount of sugar. At present, five weeks after admission, the child showed a gain of 10½ pounds in weight, has recovered her strength, is much brighter mentally, and showed in every respect great improvement. She is, of course, by no means cured, but the fact that it was possible to keep her urine free of sugar and at the same time have her gain in weight and strength justifies the hope that under careful supervision she may gradually acquire the power to use a sufficient amount of carbohydrate food to enable one to provide her with a permanent diet which is both acceptable and adequate for her needs. The case furnished another illustration of the great value in certain cases of the oatmeal diet in aiding in freeing the urine of sugar. It also illustrated the great importance in a case such as this of hospital supervision and discipline. Under the control of tactful nurses in the ward it was not difficult to have the child adhere to the very strict diet required and still to eat enough for all her requirements.

Dr. C. L. DANA said that he remembered a case of a boy 16 years of age. The patient passed a tremendous amount of sugar. Under a carbohydrate regulation the same condition was brought about as was presented in the case exhibited. There was, too, the gain in weight.

Dr. L. A. CONNER said the child had been mentally deficient all her life, and he could not state just why she had suddenly developed a severe diabetes.

Specimens of Growing Organs Outside of the Body.—Drs. ALEXIS CARREL and MONTROSE T. BURROWS stated that a few weeks ago they had succeeded in cultivating outside of the body adult tissues of mammals and malignant tumors of fowl and man. The starting point of their researches was the work of Harrison on the embryonal tissue of the frog. They adapted his method to warm-blooded animals and used it for the cultivation of adult normal and pathological tissues. The experiments consisted of extirpating small fragments of tissues, of inoculating them aseptically into a plasmatic medium taken from the same animal and of sealing the materials in hollow glass slides. The slides were placed in an incubator, maintained at a constant temperature of 37°. The growth of the cells could, therefore, be observed and the multiplication of the cells directly seen, during a period of time, with the microscope also kept at body temperature. Connective tissues, cartilage, peritoneum, bone-marrow and bone, skin, thyroid gland, spleen, suprarenal kidney, liver, ovary, testicle, etc., were cultivated successfully. They obtained also a second generation of cells from thyroid cells already grown outside of the body. A very malignant fowl sarcoma was caused to grow luxuriantly outside of the body. The rate of the growth might be very rapid. In one case the surface covered by the new cells, eleven hours after the inoculation of the culture medium, was fifteen times larger than the area of the primitive fragments. It had been also possible to cultivate fragments of a human sarcoma, so one might be able to study *in vitro* the growth of the various human malignant tumors.

Dr. J. D. BRYANT said that he was attracted by the statement that the knife which was employed in cutting the chorion had carried into the chorion cells of the other structure, and that these cells were implanted in its structure. This was very important, as it emphasized the importance of keeping one's instruments sterile.

Dr. CARREL said the tissue grew much faster in a culture from the same animal, and when they used plasma from the same animal they obtained positive results, but when tissue from a chick was used in a culture from an adult chicken the result was negative.

SOME RECENT EXPERIENCES WITH THE NEW SPECIFIC REMEDY, EHRLICH 606.*

BY SAMUEL W. LAMBERT, M.D.

NEW YORK.

THE presentation of a report to this Society on the new remedy of Ehrlich known as 606 based only on a short clinical experience can be justified in part by the rapidity of action of the drug, but more particularly by the great interest which has been roused in the medical world by this new conception of its discoverer. Ehrlich has added another brilliant achievement to his list of successes. Not only has he formulated a new idea in therapeutics christened by him a *therapia sterilisans magna*, by which he proposes with a single dose to destroy the germs of a disease that untreated would outlast the life of the individual and be transmitted to his descendants. But also Ehrlich has given us the remedy which tries to accomplish this seeming impossibility as viewed by former medical standards.

Never before have such numbers of reports from various medical sources been so unanimous in support of the claims for a new therapeutic measure. The future may show that the claims for the method and the drug are exaggerated, but enough is known to prove the principal facts that the large majority of syphilitic patients may be freed of all visible signs of the disease by the injection of a single dose of Ehrlich 606. In this paper it is proposed to review the question from a practical standpoint and to report a few typical cases.

One of the most interesting features of the subject is to be found in a study of the theoretical considerations by which Ehrlich reached his conclusions of the possibility of a single curative dosage. He began his work in this line of study on trypanosomes and sought for remedies which would be parasiticide on the one hand and on the other would not destroy the tissue cells of the host. Ehrlich has invented two new terms to express these ideas, "parasitotropic" and "organotropic."

The group of parasites to which the spirochetes belong includes the malarial plasmodia as well as the trypanosomes. Attention had been called to the use of arsenic as atoxyl in the trypanosomiasis of sleeping sickness and from this starting point Ehrlich began to experiment with chemical substitution products.

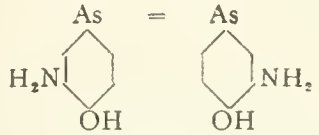
He found also that this group of animal parasites would become immune to arsenic compounds when the drug was given in divided doses; he therefore sought for a drug which would be so strongly parasitotropic and so weakly organotropic that in a single dose it would kill all the disease germs present in the body of the patient while sparing the many tissue cells of the host.

His first success was with trypanosomes in mice and with a new remedy named "trypan-red," with which he first successfully sterilized with a single dose the living mouse after trypanosome infection. He then turned his attention to other members of this group of parasites, notably the spirochetes, and to the treatment of syphilis.

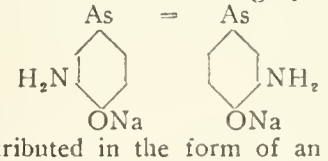
Ehrlich has experimented with more than 630 remedies and No. 606 on this list has seemed to fulfill the condition most accurately.

The testing on animals having proved its usefulness it was given to man and the new therapeutic idea of a *therapia sterilisans magna* was made public.

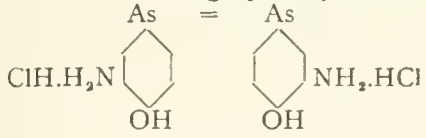
This remedy is a preparation of arsenic to be known chemically as dioxydiamidoarsenobenzol—its chemical formula is $C_{12}H_{12}O_2N_2As_2$ arranged graphically thus:



Its alkaline salt with sodium is graphically this:



It is distributed in the form of an acid salt, a dihydrochloride, schown graphically thus:



This acid salt is a yellow powder which oxidizes on exposure to the air and it must be preserved in vacuum tubes. This acid salt must be changed to the alkaline sodium salt or to the insoluble base suspended in a neutral mixture before it is injected or its administration will be very painful or even devoid of result. In one case known to the writer the preparation was faulty and a large swelling resulted at the seat of injection. After some days this was incised and a quantity of the remedy was found in a cavity with necrotic walls.

The preparation of the individual dose should be done immediately before injecting it either as the base itself after the method of Wechselmann or as the alkaline salt in the manner of Lesser. In both methods sterile utensils must be used and the strictest asepsis observed.

The Wechselmann method consists of neutralizing the acid salt with sodium hydrate and then suspending the resulting base in sterile water, which is neutral in reaction.

*Read at a meeting of the Practitioners' Society of New York, December 2, 1910.

The most efficient method seems to be that of Lesser and consists of the preparation of a solution of the alkaline salt in as nearly neutral a solution as possible. The detail of the Lesser method is as follows: Dissolve the 606 salt in 15 c.c. of hot water in a sterile glass stoppered and graduated cylinder, then add 2 c.c. of normal solution of sodium hydrate. At first a precipitation occurs which disappears upon the addition of a sufficient quantity of the sodium hydrate. This should be added drop by drop until a clear solution is obtained, which should be neutral in reaction. This is diluted with sterile water to 20 c.c. and injected, preferably in the buttocks.

The dosage is from 0.35 gram to 0.6 gram for adults and proportionally reduced for children. A recent publication by Duhot of Brussels gives 1.0 gram as the regular dose for a strong, otherwise healthy man. The dose for nursing children should be at least one-twelfth the smallest adult dose; it is to be estimated at 0.008 gram per kilogram of weight. The nursing child can be cured of its hereditary syphilis through the mother's milk after the

Fig. 1.—Case I, Hereditary Syphilis

mother has received an injection, but in severe cases and in bottle fed children an injection must be done.

The injections have been made intravenously, intramuscularly in the gluteal region, and subcutaneously in the interscapular region. In the first four cases quoted below the injections were given subcutaneously and the drug was reduced to the neutral base, in the fifth case the 606 was injected as the alkaline salt.

The known power of the original arsenical parasiticide of this series—atoxyl—to cause an atrophy of the optic nerve has led to a certain suspicion against all arsenic-containing drugs, and Ehrlich 606 has been carefully studied to discover such an effect if present. No such cases have been reported in the literature, but Ehrlich has formulated certain precautions to be observed in the use of the drug both because of this tendency to cause optic nerve disease of other preparations of arsenic and because the drug has hastened death in persons suffering from chronic disease of the heart, the kidneys, and the nervous centers. These indications for care and caution in its use are the following: Signs of disease of the optic nerves; advanced disease of the heart or kidneys; tuberculosis, old age or cachexia from any cause, and disease of the

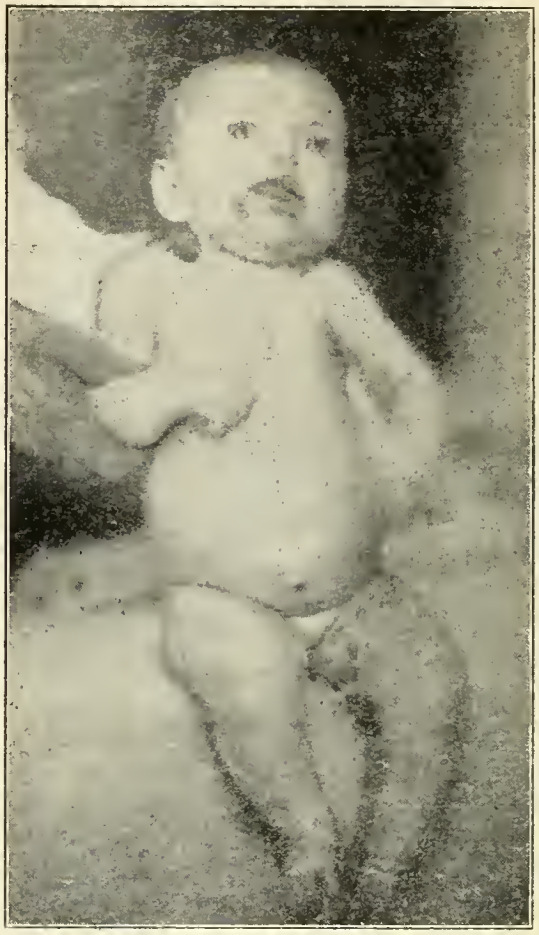


Fig. 2.—Case I, Hereditary Syphilis.

brain, even if that be of syphilitic nature. It is to be expected that such a powerful remedy should show some manifestations during its use. These therapeutic symptoms are pain, which is extreme if the acid salt is used, and may require morphine for its control. There is a local reaction, with swelling

Fig. 3.—Case I, Hereditary Syphilis.

and evidences of an inflammation, but an abscess should not result if the injection is aseptically done and the drug is properly prepared. An eruption may follow which may be either a local erythema or a

general urticaria and sometimes a reddening of the syphilitic rashes may result.

General symptoms of fever even to 104 degrees, of headache and gastric disturbances may last for

Fig. 4.—Case II, double chancre of lip before first injection.

several days. The patient is often constipated and may have difficulty in urinating during the same period. Two further precautions should be noted: The patient should be in bed under observation during this period of reaction and the diagnosis of syphilis should be established with every aid from the Wassermann test, and the examination for spirochetes. The results of treating syphilis with Ehrlich's arsenobenzol have been rapid and wonderfully uniform. All observers unite in the opinion that the method and the remedy show a specific action against syphilis which is remarkable.

The drug has been in use just over one year and recurrences and incomplete cures are beginning to be reported, but nevertheless the enthusiasm of the medical men reporting such semi-failures is still unbounded.

Under this treatment the spirochetes disappear from the lesions, both primary and secondary, in from twenty-four hours to seven days, and the Wassermann reaction changes from positive to negative in from 12 days to seven weeks. The action on primary chancres seems to vary with the age of the infection. An early infection is more difficult to influence than a chancre which has run its first period of induration.

It has been suggested that such chancres with extensive induration be excised as a help in the cure. When not excised a second dose has been found necessary. The secondary lesions have usually yielded quite promptly to a single dose. The tertiary lesions also have been quickly influenced for cure by 606 according to reports of all observers. The future course of the disease cannot be formulated at present, for no "cure" under the old treatment with mercury and iodide could ever be considered as a cure until at least two years had elapsed after the cessation of treatment. Arsenobenzol has been in use only fourteen months and it has not been possible to apply this test of time, which cannot be omitted from the study of these cases if a true conclusion is to be reached.

The following cases present many points of interest in this treatment:

Case I.—*Hereditary Syphilis.*—Female child 2 months old.—Parents have been married one year; this is the first and only child; baby has been breast fed. At birth baby had a severe coryza. At seven weeks of age a rash came on the feet and hands which has spread gradually over the extremities, the face and the chest. The rash does not itch. Physical examination shows a fairly well nourished child covered with a dull red rash occurring in irregular confluent patches, which are slightly raised. The rash is general except the abdomen, and is not plentiful on the chest and back. There are bullæ on the thighs and the palms and soles are desquamating in large flakes. The mucous membranes are free; except for labial fissures there is a typical mucous patch on the left hip. The liver is enlarged two fingers below the costal margin and the spleen projects four fingers below the ribs. There is tenderness at upper epiphysis of humerus. Lymphatic glands are not enlarged. The anterior fontanelle is open, the eyes and ears are negative to examination. The nose is swollen and there is a nasal discharge. The baby's cry is hoarse; the heart and lungs seem normal.

The child had a fever from 100 to 102 for two days. A white blood cell count showed 32,000 leucocytes, with 7 per cent. polymorphonuclears and 93 per cent. lymphocytes, with normoblasts and megaloblasts. The Wassermann blood reaction was positive, but spirochetes were not demonstrated. On the third day of observation 25 milligrams of the arsenobenzol was injected under the skin of the back. No special reaction followed except local tenderness. Patient began to improve at once in all particulars, the hoarse cry lessened and the skin became less angry looking; ten days after injection the baby is much improved in the appearance of the face, the fissured mouth is almost healed, the liver and spleen are smaller. The white blood cell count is 20,000, with polymorphoneutrophiles 33 per cent., lymphocytes 65 per cent., eosinophiles 2 per cent. Three weeks after the injection the baby appears with normal skin and mucous membranes and no coryza, with no enlargement of the liver or spleen. Her blood shows still a Wassermann reaction. The blood of both the father and mother were negative to the Wassermann reaction. The

Fig. 5.—Case II, slight improvement from first injection at time of second injection.

father admits having contracted syphilis eight years previously, for which he was treated one year and a half.

Case II.—*Primary Syphilis.*—A man 32 years

old.—Thirty-one days before admission he noticed a small red sore on each lip; several days later a swelling came under the right angle of his jaw; he has had no rash, but has suffered from headache,

Fig. 6.—Case III, chancre of lip before first injection.

poor appetite, and pain in lip at night. Thinks he had a chancre nine years ago, with only a short period of treatment; he has had smallpox and measles. Physical examination is negative except for two ulcers; one about 1 cm. in diameter is to the right of the center on the upper lip, and one about 1½ cm. in diameter is on the left side of the lower lip; both are on an indurated hard base and covered with greyish sloughs. Both lips are greatly thickened and bulge out with the induration. Two large glands and many small ones are felt in the neck, submaxillary region, and especially on the right side. There is no skin eruption. Smears from the ulcers show spirochetes, and the Wassermann test is positive. The white blood count is 13,700, with polymorphonuclears, 63 per cent., lymphocytes, 32 per cent., eosinophiles, 5 per cent. The urine shows a faint trace of albumin. The eye grounds are normal. An injection of 0.6 gram of arsenobenzol was made on admission. There was a local reaction, with pain and redness, and a febrile reaction up to 101.8° for 24 hours.

Six days later the patient was discharged with slight improvement in the local condition, if any. At this time spirochetes were demonstrated again in the lesion. He was readmitted 14 days later; the condition of the chancres on the lips was practically unchanged; the glandular swellings under the jaw were slightly smaller. There was an eruption covering the entire chest, abdomen, and all but the lowest part of the back. This rash is a typical dull red maculopapular secondary syphilis.

The Wassermann test was still positive and spirochetes were found in the smears from the labial ulcers. The white blood cells count was 8,000, with a differential of polymorphonuclears, 66 per cent., lymphocytes, 29 per cent., eosinophiles, 4 per cent., basophiles, 1 per cent. A second injection of 0.6 gram of 606 was followed by a slight febrile reaction to 100.2° for 24 hours. Improvement has been slow—two weeks after the injection the rash has faded materially, but smears from the lip do not show spirochetes. The induration about the chancres has diminished. There has been no marked change for the better, although slow improvement is going on.

Case III.—*Primary Syphilis.*—A woman, age 27. —Six weeks ago she noticed a small sore on the lower lip which was red and about three-eighths of an inch in diameter. This sore has persisted and gradually grown larger, and has exuded a thin, purulent fluid. Ten days after onset the glands under the jaw began to swell and be painful and she soon developed headaches, which continue. Five days before admission she first noticed an eruption on the abdomen. Physical examination showed all organs negative except a palpable spleen. There was a small indurated ulceration on the left side of the lower lip, the submaxillary lymph nodes are enlarged on the left side; no lesions in other glands or in the mouth. There was a maculopapular syphilide over the whole trunk of the body.

The Wassermann reaction was positive, but spirochetes could not be demonstrated in the ulcer on lip. The white blood cell count was 15,000, with a differential of polymorphonuclears, 76 per cent., lymphocytes, 24 per cent. An injection of 0.5 gram of 606 was followed by local pain for 48 hours and a febrile reaction to 100.8° for 24 hours.

Improvement has been rapid. The rash had disappeared at the end of four days and the primary lesion was distinctly smaller and softer after three days. This improvement has continued up to the present time.

Case IV.—*Tertiary Syphilis, Dactylitis, Orchitis.*

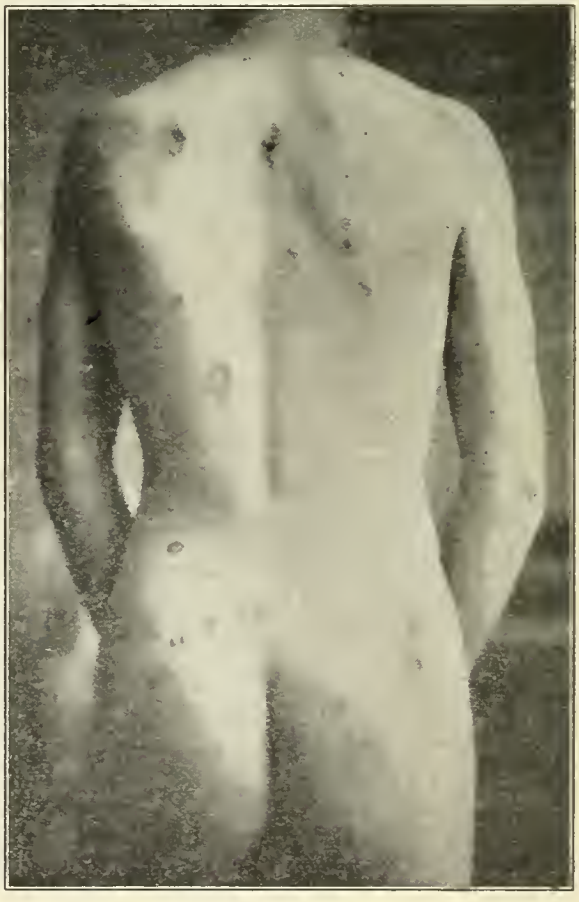

Fig. 7.—Case V, tertiary syphilis resistant to mercuric treatment.

—A man, age 27.—Had chancre six years ago, followed by rash and sore throat in three weeks. Since then has been under continuous medical advice and has taken mercurials as directed in an inter-

mittent manner, both by mouth and by inunction until four months ago. Three months ago he noticed a swelling of the index finger of the right hand, which persists in spite of an incision, which is now healed. During past three years there has been an intermittent swelling of the right testicle, which is now extreme. Patient took an atoxyl cure for a month, four months ago, with no result, and has had no treatment for three months.

Physical examination shows no gross lesions of the organs; there are some pigmented scars on the legs. The first interphalangeal joint of the index finger of the right hand is twice its normal size; the swelling tapers off toward the tip; the swelling is hard and moderately tender, and the other joints of the finger have a limited movement. The right testicle is swollen, hard, and tender, and there is a hydrocele in addition. The blood shows a positive Wassermann reaction; the white blood cell count is 12,600 and the differential is, polymorphonuclears, 77 per cent., lymphocytes, 22 per cent., eosinophiles, 1 per cent. An injection of 0.5 gram arsenobenzol caused a marked local reaction, with a febrile rise to 100.2°.

The patient was convinced twelve days later that both lesions were improved. The dactylitis seemed distinctly better, with less swelling and tenderness. The orchitis has not been affected.

Case V.—*Tertiary Syphilis.*—A man, age 30.—Patient contracted syphilis March 24, 1910; his chancre developed with bilateral inguinal buboes and was followed in a month by a sore throat and a roseolar eruption on the chest, abdomen, face, back, and extremities. He had headaches and a fever and felt weak and tired. He has lost 31 pounds in weight in the past eight months.

The treatment was begun energetically, with mercurial inunctions. His specific symptoms did not yield and he developed a dermatitis and a stomatitis. He was then put on subcutaneous injections of mercury, on which he improved. Three months after his infection he noticed, while still under hypodermic treatment, four small ulcers on his forehead, which healed after a short interval. One month later a bluish red swelling appeared on the forehead, which became necrotic in the center and formed a circular ulcer, which persists two months later. During the past two months similar hard lumps, and also some serpigenous tertiary syphilis, have appeared on the scalp, the cheeks, the back, and the legs, which persist either as indurated places or as ulcers. The progress has been steady from bad to worse in spite of continued treatment with mercury until the present time.

Physical examination showed a general enlargement of the lymph glands and no other lesions except on the skin. The entire body is studded with tertiary syphilides varying from one to five cm. in diameter. There are two punched out ulcers on the scalp which are moist and partially encrusted with scabs. The largest ulcer is on the left calf and is secreting considerable pus. Some of the smaller ones are partly healed. The Wassermann was positive, but spirochetes were not demonstrated.

An injection of 0.4 gram of 606 in the form of the sodium salt was followed by a severely indurated and painful local swelling, with a general febrile reaction to 103.6° for three days. He required analgesics to secure sleep. The eruptions began to improve at once and at this time, five days after the injection, the patient is sure that his improvement has been more steady than ever before. The ulcers are secreting less and granulating in a more healthy way. The largest one is beginning to cicatrize.

These five cases represent the three principal groups in which arsenobenzol seems particularly indicated. First, the hereditary case, in which the results are most striking. Second, the primary lesions, of which two cases are reported. One (No. 3), a case of slight sclerosis about the chancre, seemed at last interview to be recovering rapidly. The other case is one with a heavy induration at the base of the chancre. The slow improvement, even after two injections, bears out the conclusion of several observers that chancres in the stage of induration are more difficult to influence with 606 directly in proportion to the size of the sclerosed tissues. The third group of cases is the type which either bear mercury ill or which are not influenced by mercury.

Case IV would, under any conditions, be difficult to cure, and Case V promised to show marked benefit from a single injection after a severe course of mercurial therapy had entirely failed to control the disease.

Case II also would lead one to adopt a larger dosage in large, robust men, as has been done by Duhot, who, as already pointed out, has given as high as 1.1 grams at a single dose, and only with benefit.

The question of excision of the chancre as an aid to early cure in these cases should be considered and this has also been advised.

These patients were tested further in reference to the excretion of the arsenic by the urine. In four cases tested in this way arsenic was found in the urine within two hours of the injection, and in two cases which remained in the hospital long enough for observation the arsenic had disappeared from the urine after fourteen and twenty days respectively. Whether these facts have any bearing on the duration of the influence of this method of a single dosage or on the period as to when a second dose should be given, if at all, must be decided by a larger clinical experience than is afforded by five cases.

It is possible to report, four weeks after reading this paper, that Case I of hereditary syphilis and Case V of the very resistant tertiary type are free from visible manifestations of the disease. The skin lesions in both cases are healed. Case IV is not improved, and Cases II and III are free from chancre induration, but some glandular swelling and some cutaneous macular eruption still persist in Case II, the one which received the two doses of the drug.

The general conclusion to be formed from these cases is an endorsement of the universal verdict of medical observers, that Ehrlich has added a remarkable remedy to the treatment of syphilis and has formulated a new idea in parasitic specific therapeutics.

130 East Thirty-fifth Street.

A Red Cross Car.—The American Red Cross Society has recently put in operation a special car, donated by the Pullman Company, for use as a traveling first-aid school. The car is fitted with all sorts of first-aid appliances. It is in care of Dr. M. W. Glasgow of Birmingham, Ala., who visits in it various manufacturing and mining centers, stopping at each place long enough to institute classes in first-aid and to interest the local physicians who will maintain the classes after the car has gone.

SOME PRACTICAL POINTS IN THE TREATMENT OF DISEASES OF THE HEART*

By EDWARD E. CORNWALL, M.D.,

BROOKLYN, N. Y.

VISITING PHYSICIAN TO THE WILLIAMSBURGH AND NORWEGIAN HOSPITALS.

The treatment of diseases of the heart is mostly symptomatic, but the same symptom is often produced by quite different pathological conditions; so in order to treat heart diseases to the best advantage it is necessary first of all to make an accurate diagnosis; for treatment of a particular symptom beneficial in one condition might not be at all suitable or even injurious if given for that symptom when due to some other condition. For example, cardiac insufficiency, due to lost compensation in chronic valvular disease occurring in a young person with a fairly good myocardium, should not be treated in the same way as the same condition due to advanced myocardial degeneration in an elderly person. Nor is the treatment of cardiac insufficiency due to mitral incompetence quite the same as that called for when this symptom is due to stenosis of the same valve. The treatment of arrhythmia due to gastric dyspepsia or intestinal autointoxication differs radically from that which should be prescribed when the same symptom is due to acute or chronic myocarditis. And dilatation due to sudden cardiac strain and dilatation due to the long-continued overexertion to which the heart is subjected in chronic interstitial nephritis differ notably in their therapeutic indications.

The most extensively useful remedy which we have for the treatment of heart diseases is rest. This remedy is indicated wherever cardiac insufficiency is a symptom, which means in most cases of serious heart disease. It is often the only medicine required. This remedy has a wide range of dosage as prescribed for different conditions; and also the period during which it should be taken varies much in length. Insufficiency due to decomposition in valvular disease occurring in children calls for rest in practically unlimited dose, that is, the patient should be kept absolutely in bed as long as possible, at least for one month after all symptoms of insufficiency have disappeared. Patients in middle or advanced life should not be kept in bed so long or so rigorously, and many such patients with only a moderate degree of insufficiency do best if allowed to be up and around with more or less restriction of activity. In aged patients with myocardial degeneration prolonged stay in bed may seriously increase the weakness of the heart. In any case of acute endocarditis rest in bed for at least one month after the subsidence of all symptoms, even if there has been no noticeable insufficiency, is good practice. Fine judgment is often required for the accurate prescription of rest, but on the whole it is better to err on the side of giving too much than too little; the error most frequently made is in giving too little.

Formal exercises, active and passive, and massage can be employed to increase the margin of reserve in cases with imperfect or fragile compensation. They are specially valuable in walking cases of myocardial disease. They can be used with benefit in valvular disease during the period between the recovery of the circulatory balance while the patient is in bed and the time when sufficient compensation is secured to make it safe for him to be up and around. Massage and resistance exercises given to such a patient while in bed take away the sharpness of the transition, as regards the strain on the heart, when he changes from the horizontal to the vertical position. Incidentally they counteract the general muscular weakness and atrophy, which naturally result from long continuance in bed. While these exercises and massage are of very great value in certain cases, there exists a tendency to overrate their value and to use them in excess. They are rarely required in children. In adults they are indicated only when the patient's condition is so delicately balanced that he cannot safely be allowed to graduate his own exercises. When the physician prescribes them he should see that they are not given too vigorously. If given by a professional masseur his performance should be supervised by the physician sufficiently to make sure that it is not overdone. In many cases some member of the patient's family or the nurse can be taught to give the massage or the exercises, and they can be more safely trusted, as a rule, to watch the effect on the patient's condition than the professional masseur.

In connection with the use of formal exercises and massage in the treatment of diseases of the heart the subject of the Nauheim baths naturally arises. For a number of years the writer has held and expressed the opinion that this remedy was greatly overrated, that its usefulness was limited, at the best, to a very small class of cases, and that the inconveniences and even dangers which attended its use, except in the most carefully selected cases, were sufficient to warrant us in disregarding the large claims made for it by its promoters, notwithstanding the extensive approbation with which those claims have been received by the medical profession, which, however, does not generally use this treatment. The Nauheim baths figure in our textbooks as a standard remedy whose value is unquestioned, but the writer repeats a former prophecy that the time is not far off when the textbooks will give them less conspicuous mention, perhaps relegate them to the historical sections, where so many once "standard remedies" are unnecessarily kept in remembrance for a while. Holding this opinion, he was interested to read in Mackenzie's excellent book on "Diseases of the Heart," recently published, the following statement.

"I feel it would be misleading if I passed in silence a method of treatment that has obtained a world-wide reputation which I consider out of proportion to its merits. Though I enter into the matter reluctantly, I conceive it none the less a duty, particularly as I am impressed with the injury done to individual patients through the unmerited reputation of the Nauheim baths among the medical profession. In the patients entering the baths I could discover no improvement from the single immersion. I may frankly confess that I saw no patient get benefit at Nauheim that would not have done equally well elsewhere."

The question of diet in heart diseases depends usually on the condition of the gastrointestinal tract and the irritability of the heart. Passive congestion due to valvular or myocardial disease may be so great that only peptonized milk or other predigested foods are tolerated. The myocardium may be so irritable from degeneration or dilatation that moderate distension of the stomach results in serious disturbance, either by mechanical pressure or nervous

*Read before the Long Island Medical Society, November 1, 1910.

reflexes. In such cases frequent small meals of easily digested food should be given. In any case in which compensation is not well established the passive congestion present in the liver and kidneys suggests a diet in which animal proteid is highly restricted, in order to limit the production of putrefactive products whose elimination would burden those weakened organs. When there is much edema the diet obviously should be as dry as is consistent with comfort; and in any case of cardiac insufficiency, particularly when due to degeneration of the myocardium, excess of fluids should be avoided; and in any case in which there is reason to believe that the myocardium is weak, as in typhoid fever or pneumonia, though the symptoms of cardiac insufficiency may be absent, the administration of very large quantities of fluid to flush the kidneys is bad practice, for the work of pumping the excessive quantity of fluid through the kidneys falls on the heart.

Drugs which act on the heart occupy a position of relatively great importance in cardiac therapeutics. They are given to increase systolic activity and power, to diminish cardiac irritability, and to dilate the arteries. Drugs given to dilate the arteries act as stimulants to the heart, in the sense that they diminish the resistance against which it works.

Digitalis has been allowed first place among heart drugs for more than a century, but its extraordinary effectiveness as a heart stimulant in certain conditions has led to its abuse. I think it is not unlikely that the majority of the doses of this drug, which have been prescribed since Withering's celebrated monograph was published in 1775, have done more harm than good. To get the benefit of this most valuable remedy it should be prescribed with a clear understanding of its indications, limitations and contraindications.

Its prime indication, and almost its sole one, is chronic valvular disease with cardiac decomposition which is too extensive to be restored by simple rest in bed in patients whose myocardium is not much degenerated. It can be used in some other conditions, but in these it is of secondary importance; and in chronic valvular disease it is not always the remedy of choice. In organic mitral incompetence occurring in youths or young adults, but not in children, it usually acts better than any other drug, particularly if the lesion is extensive. In aortic lesions it may or may not act well. In acute dilatation of the heart from any cause without marked degeneration of the myocardium it is often the best drug. In the failing heart of pneumonia it is one of the last heart stimulants to use, but in bad cases it may help.

The contraindications to the use of digitalis are: Ability of the heart to recover compensation by rest alone; childhood and old age; the existence of much myocardial degeneration—it is particularly injurious in fatty heart, acute endocarditis, mitral stenosis, usually, atheromatous arteries, high blood pressure, and irritability of the stomach.

Probably the most common abuses of digitalis are its administration in cases which can compensate without it, in cases in which myocardial degeneration exists, and in cases in which there is already high blood pressure. Many seem to think that they must immediately prescribe this drug whenever they find symptoms of cardiac insufficiency, without regard to the extent of the insufficiency or the character of the underlying condition.

The preparation of digitalis which is used matters little, provided it is reliable. For general prescription the tincture is probably as reliable and convenient as any. The common prejudice in favor of the infusion does not seem to be justified, at least, considering the manner in which that preparation is often dispensed. The range of dosage of digitalis is rather large and directions regarding the dosage cannot be given in a few words. Extensive practical experience is necessary to give anything like precision in its use. The following suggestions may, however, help: Give it in doses large enough to produce the desired effect; do not expect to produce the full effect immediately; do not keep it up if the symptoms grow worse under its use; do not keep up its administration too long.

Strophanthus shares with digitalis the primacy among heart stimulants. The power of digitalis within its narrow range is perhaps greater than that of strophanthus, but the wider range of the latter at least equalizes their value. Strophanthus can be used like digitalis to restore lost compensation in chronic valvular disease and in some forms of valvular disease, particularly mitral stenosis and aortic stenosis and incompetence, it is usually the more effective of the two, and in all forms of valvular disease in children it is the better drug. It is much more useful than digitalis in the myocardial conditions produced by the acute infections, and it is often of great value, if used cautiously, in the chronic degenerations of the myocardium. High arterial blood pressure is not a contraindication to its use. In the comparative infrequency with which it disturbs the stomach, and in its freedom from cumulative action, it possesses notable superiority over digitalis. In short, it does nearly everything that digitalis does and a great deal more besides, and does them more pleasantly and more safely.

The effective dosage of strophanthus is considerably smaller than that given in the textbooks, most of which advise 3 to 10 minims of the tincture. The dosage which will be found to give the best results in ordinary cases is 1½ to 3 minims every 4 hours. It is seldom that we can with advantage exceed 3 minims as the dose unless the drug has been given for a long time, so that the patient has acquired a tolerance. It should be given at intervals of 4 hours, for it is rapidly eliminated. Failure to get good results with strophanthus are probably due in many cases to the fact that the doses given were exclusively large, following the mistaken general notion of its dosage. For the widely diffused myth that the preparations of strophanthus are unreliable I have found no adequate foundation in fact. The preparations of it, made by reputable drug houses, which have been dispensed on my prescriptions have answered expectations.

Strychnine is perhaps the most extensively used of important heart stimulants. It is a much less powerful agent for increasing the cardiac systole than digitalis and strophanthus, which act directly on the heart muscle; its effect is brought about through the nervous system, through the increased irritability and responsiveness which it produces in the nerve centers, but its wide range of usefulness, together with its freedom from disagreeable or untoward effects, put it in the first class with the two heart stimulants just mentioned. It is the best drug for fatty heart and most conditions of myocardial degeneration, acute and chronic, though in those conditions it may require help from other heart stimulants. It can be used as an adjuvant to

digitalis and strophanthus in valvular disease. It produces no disagreeable effects on the stomach nor, if given in proper doses, on the nervous system. It does not increase arterial tension; in fact, in arteriosclerosis it may lower arterial tension, probably by improving the nervous control of the circulation. This result I have personally observed. The dosage ordinarily ranges from one sixtieth of a grain of the salt 3 times a day to one thirtieth of a grain every 4 hours. It is rarely necessary to give it in larger doses, except in certain emergencies and after tolerance has been established. Tolerance of half a grain a day can be acquired in a reasonable time, but my experience leads me to believe that even after long-continued use few patients will bear well a total daily administration of much more than half a grain.

A few people have an idiosyncrasy in regard to strychnine and cannot take even as large a dose as one sixtieth of a grain without having intestinal cramps; and a greater number cannot take doses of one thirtieth of a grain without disagreeable consequences; but considered from all points it is probably the safest, as well as the most widely useful, though not the most powerful, of heart stimulants.

Digitalis, strophanthus, and strychnine are the three most useful heart stimulants that we have. There are, however, several other drugs which posses merit as heart stimulants which can be used to take the place of or to aid these three. Of the lesser heart stimulants I will mention those which I consider most worthy of being kept on our list. There are still others in good use which I shall not mention and this omission does not mean that they have no value as heart stimulants, but that their value is slight, or that their action is covered by better drugs. Caffeine is a particularly useful drug. It acts something like digitalis and strophanthus and very quickly. It has no unpleasant side effects. It can be given to aid or replace digitalis and strophanthus. It is pre-eminently useful as an emergency stimulant. Aromatic spirits of ammonia is the only ammonia preparation which I use as a heart stimulant. It can be given in frequently repeated doses in conjunction with other more powerful drugs. Alcohol may be used sometimes with advantage in the myocardial weakness which results from the toxemias of the acute infections, and also in some chronic myocardial degenerations, particularly those included in the term senile heart.

Morphine as a heart stimulant stands in a class by itself. It deserves mention with digitalis, strophanthus and strychnine for the great good it can do in heart diseases, though its use is generally restricted to cases of extreme insufficiency. In many cases it is the one thing needful to tide the patient over a critical period until recovery of compensation begins. It acts partly, no doubt, by diminishing the bad effect on the unbalanced heart of disturbing nervous reflexes, and also, when given in considerable doses, by greatly diminishing the need of the body for oxygen and thereby lessening the necessary work of the already overworked organ. In chronic valvular disease its main indication is extreme decomposition which does not improve under rest and stimulation; in these cases it is best given in small doses, one twenty-fourth to one-twelfth of a grain every 4 hours, for an adult; it will allay the dyspnea and the irritability of the myocardium. It is sometimes required in mitral stenosis before the decomposition has become extreme, and in acute endocarditis with an extremely irritable heart it is often called for. In the impending heart failure of pneumonia it may prove of great value. For extreme cardiac dyspnea, due to myocardial disease, which is not relieved by ordinary remedies, it is the only drug on which we can fall back with confidence. Here it should be given in doses sufficient for the purpose. In advanced fatty heart, in coronary sclerosis, and fibroid degeneration of the heart it may temporarily restore a patient who is in an apparently hopeless condition. In these cases it is sometimes necessary to run up the dose rapidly, even to a total of 1 or 2 or more grains a day.

Morphine is a cardiac sedative as well as stimulant, as I have said, but it is not the best drug to use in every case in which we need a cardiac sedative. For irritability of moderate degree occurring in fatty heart, cardiac sclerosis, and aortic sclerosis, cactus has seemed to me a particularly useful drug. I always prescribe the tincture of the green plant. Cactus has been classed among the heart stimulants, but I believe that it is better placed among the sedatives.

Aconite is a useful cardiac sedative, but it should never be given if there is heart weakness from any cause. Its indications are found in the overaction of the heart observed at the beginning of some of the acute infectious diseases, in the overaction of the heart observed in some cases of chronic interstitial nephritis with high blood pressure, and in some cases of cerebral hemorrhage with high blood pressure. Aconite properly used is a very valuable drug. It has a wide range of dosage—from one-tenth of a minim to 10 minims. Given in doses of one-fifth of a minim every half hour in the beginning of coryza, tonsillitis, or pneumonia, it may produce pleasantly surprising results. In chronic interstitial nephritis with high blood pressure it should be given in the larger doses, from 2 to 10 minims every 4 hours.

Vasodilators are negatively heart stimulants. This is notably the case with amyl nitrite and nitroglycerin, whose paralyzing effect on the myocardium is so much less than their effect on the arterioles that the difference amounts to a substantial reduction in the arterial resistance. The easement of the heart's labor produced by a single dose of nitroglycerin is transient, lasting probably less than half an hour, so the dose should be repeated often. The size of the dose is best measured by the effect, and large ones may sometimes be given with safety and advantage; but even small ones are not always well borne, especially in cases of chronic interstitial nephritis with high blood pressure and a greatly hypertrophied heart; in such cases it sometimes produces a distressing sense of fulness in the head. In most arteriosclerotic conditions it acts well. Of the nitrite group, only the two above mentioned should be used. The others are dangerous heart poisons.

The drugs which I have mentioned are, in my opinion, the best of those which we have that act on the heart. If we learn how to use the drugs in this preferred list we can without much loss neglect the rest, though a few of them, notably atropine, camphor and ether, might put in a reasonable plea for occasional recognition.

In the foregoing remarks on the cardiac remedies I have given to a considerable extent my own opinions of those remedies, without attempting any-

thing like a full discussion of their merits and uses, and have tried to bring out a few only of the most suggestive points about them. I will now ask your attention to some brief remarks on the best treatment, as it seems to me, of a few particular cardiac conditions. The topics selected are taken at random from the wide field of cardiac therapeutics.

When the decompensated heart no longer improves its action under our treatment, but steadily loses ground, and the edema of the lower extremities, of the scrotum, of the back, and even of the upper extremities, becomes extreme and distressing, what shall we do? We can get no more work out of the badly damaged and exhausted pump; purgatives help a little, but not much; diuretics act but feebly on the congested and probably cirrhotic kidneys; and the only thing left to do is to let the fluid out through the skin. For this purpose Southey's tubes are practically worthless; multiple punctures are of some use; the best method is to make fairly free incisions on either side of the tendo Achillis. These may give temporary relief, and if antiseptic precautions have been observed and the skin in the neighborhood protected and kept dry by sterilized vaseline or zinc stearate, suppuration may be postponed until the exhausted heart finally fails.

Chronic interstitial nephritis overworks the heart and causes first compensatory hypertrophy and at last dilatation and breakdown. The hypertrophied heart, with its myocardium often more or less degenerated, maintains the high blood pressure necessary to produce adequate renal elimination with difficulty and often with distress, and it frequently requires stimulation. Strychnine and strophanthus, and occasionally caffeine, in addition or substitution, are the best drugs to stimulate the heart in this condition; and aconite is the best drug with which to allay the cardiac irritability, but it should not be given too long at a time. In the final stage of cardiac breakdown we can only treat the heart on general principles.

In extensive pericardial effusion which produces marked pressure symptoms do not delay to tap. Even a small amount of fluid withdrawn may be enough to start rapid absorption. Tapping, if done carefully with rigid asepsis, ought not to be attended with much danger. In the failing heart due to chronic pericardial adhesions, strophanthus acts better than digitalis, and it may be given for long periods and in increasing doses as tolerance is established.

The treatment of mitral stenosis differs in several particulars from that of the other valve lesions. Loss of compensation is apt to be rapid, without a long premonitory period, and to be recovered from with difficulty. It is often observed to take place in the third or fourth decade, after a long period during which the lesion has caused no inconvenience. Irritability of the heart is sometimes observed out of proportion to the other signs of cardiac disturbance. Response to stimulation is often unsatisfactory. It often happens that prolonged rest in bed is the only treatment that does any good. Of the heart stimulants, strophanthus and strychnine are the most useful. Digitalis is of comparatively little use in this condition. Mitral stenosis, even if well compensated, is a contraindication to child-bearing, and no woman with mitral stenosis who has become pregnant can safely be allowed to go to term.

For the soft heart of typhoid fever strychnine in small doses, and strophanthus if necessary, are the first drugs to use. In extreme cases of heart weakness in this disease aromatic spirits of ammonia and caffeine may be added. Digitalis is contraindicated.

In supporting the heart in pneumonia, it is well to be on time and not to delay stimulation until after the heart has already begun to fail. While it is true that many cases of pneumonia will recover with no stimulation of the heart or any other medication, it is good practice to give small doses of strychnine from the third day of the disease and to add further stimulation according to the needs of the circulation. If necessary, the strychnine can be increased to one thirtieth of a grain every 4 hours, which is as much of this drug as a patient with pneumonia should take. Additional stimulation can be supplied by tincture of strophanthus in doses of 2 to 3 minims every 4 hours. Strychnine and strophanthus thus given suffice for the stimulation of the heart in most cases of penumonia, but not infrequently more stimulation is called for. Then some or all of the following drugs can be given: Caffeine citrate, 2 to 5 grains every four hours; aromatic spirits of ammonia, half a dram to a dram every 1 or 2 hours; digitalin, one one-hundredth to one-fiftieth of a grain, hypodermatically, every 4 hours; and, if the patient is old or an alcoholic, or if the toxemic symptoms are pronounced, whiskey in moderate doses. In bad cases morphine should be given, usually in small doses, every 4 hours. Morphine not only stimulates the heart, but secures sleep, loss of which can be the fatal factor, and especially in the later stages of the disease it diminishes the need for oxygen and consequently the necessary work of the enfeebled heart.

A very interesting and important clinical group of cases clusters about the root of the aorta, that most hard worked portion of the human body, which sustains the full force of the systolic jet, and during the ventricular diastole, while the heart is resting, is busy transforming the intermittent flow from the heart into a continuous flow through the arteries. Atheromatous changes in this part of the aorta are common and associated with them very frequently are stiffening and deformity of the aortic valves and sclerosis of the coronary arteries. The blood pressure in this condition is usually high. The location and extent of the pathological changes in the region described determine whether the patient has an aortic valve lesion or angina pectoris, or some intermediate condition. It is an intermediate condition to which I wish to call attention. This condition is characterized by frequent attacks of dyspnea or precordial oppression attended with moderate anginoid symptoms; the patient is suddenly taken, in the day or night, with a feeling of constriction in the upper sternal region and often a pain usually described as grinding or tearing and feels impelled to sit up and hold tight to something; and there are often pains radiating towards the shoulders and down the arms. There is no particular feeling of impending death. At first the patient may have these attacks at considerable intervals, but they increase in frequency, so that they occur several times each night or day. I have found the best drug for this condition to be nitroglycerin, given freely, with extra doses at the time of the attacks —a hypodermic tablet placed under the tongue, which often relieves the symptoms inside of three minutes. Small doses of strychnine may also be given right along to improve the heart's action and

steady the circulation; and cactus I usually give also, being inclined to the opinion that it diminishes the irritability of the myocardium in this condition. If the nitroglycerin, strychnine, and cactus fail to alleviate the symptoms, we have to fall back on morphine.

In concluding this rambling paper, I should like to emphasize the following few points:

Make the diagnosis before prescribing treatment.

Do not give heart stimulants to restore compensation when rest in bed alone will do it, except in certain cases occurring in middle or later life, when prolonged rest in bed might prove injurious.

Do not give heart stimulants after compensation has been restored.

Remember that children and young people should be kept in bed for at least one month after compensation in chronic valvular disease has been completely restored, and that they should be kept in bed for the same length of time after an attack of acute endocarditis, with or without loss of compensation.

Learn how to use the best remedies and forget the rest.

Do not give digitalis to children or to old people, and always bear in mind the limitations and contraindications to the use of this drug.

Do not exceed 3 minims of tincture of strophanthus at a dose, except in extraordinary cases and where tolerance has been established.

If you prescribe mechanical methods of treatment see that the dose is right. They can do harm in overdose as well as drugs.

Do not expect to get compensation in a badly decompensated case of valvular disease too soon; be satisfied for a while if, under treatment, the patient does not get worse; improvement in many of these cases must be slow if it comes at all and attempts to hurry it unduly only exhaust the heart.

Use the smallest dose of any remedy that will do the work.

Rarely tell a patient with serious heart disease how grave is his condition, for such patients easily lose hope and become despondent, which aggravates their condition. The family, however, should always be told, and the patient should be informed of his true condition if that is the only way to secure his cooperation in treatment.

Be slow to give up hope, at least of improving the patient's symptoms in apparently desperate conditions, and especially beware of publishing too definite a prognosis.

Cardiac therapeutics is in the majority of cases a fight against odds, but by the exercise of patience, perseverance, and especially judgment, much may be accomplished.

1239 Pacific Street.

THE TREATMENT OF CHRONIC APPENDICITIS WITH HIGH FREQUENCY CURRENTS.

By WILLIAM HARVEY KING, M.D.,

NEW YORK.

I do not intend to put forward high frequency currents as a panacea for all forms of chronic appendicitis. My purpose is simply to show that by a proper technique they will remove the symptoms in many cases, while from the permanency of the symptomatic cure it would appear that there must be a cure in fact. In this treatment the important point is the proper selection of cases. In acute appendicitis electricity has no part. Operations have abundantly demonstrated that symptoms or even physical signs are not always trustworthy indications of the exact pathology of a diseased appendix. For this reason it is not possible in every instance to select the precise cases which will most likely be benefited by high frequency currents. One point, however, is clearly in favor of electrical treatment: if the proper technique is followed no serious aggravation of the condition will result.

In a case which has recovered under the influence of high frequency currents the exact pathology may continue unknown, but those cases which have failed to improve under the treatment and subsequently have been operated upon give a clue to those pathological conditions which are not amenable to high frequency currents. The one condition above all others which cannot be treated successfully by high frequency currents is the septic. It is well known that a collection of pus may be retained within the appendix for a long time without producing other symptoms than soreness and tenderness. Treves's statement*, however, that a constant tenderness in the appendix is an indication of pus is, I think, not always true. In a number of instances I have cured cases when this was a most prominent symptom—which would have been impossible had pus been present. And right here I may say that high frequency applications furnish some very accurate diagnostic indications. If a treatment, using a low frequency of alternations and passing 1,200 to 1,500 ma. for thirty minutes, is followed by a marked reaction, an aggravation of the soreness and tenderness, and in a few hours by a slight rigor and increase in temperature from 1½ to 3 degrees, it is an indication that pus is present. I have demonstrated this in three cases, subsequent operations revealing the presence of pus. Treatments with low frequencies may produce an aggravation of certain symptoms when pus is not present, but there is always a lack of the rigor and fever.

Misplacement and malformation of the appendix, of course, cannot be successfully treated by high frequency currents. Also it is thought that some cases of recurrent appendicitis are due to an attempt to evacuate a collection of fluid within the appendix, the contractions being accompanied with all the symptoms of spasm such as pain and soreness. Cases of this description would not be the most promising for high frequency currents. Undoubtedly the treatment is best adapted to cases of a chronic congestion with perhaps some adhesions. Whether high frequency currents are capable of removing adhesions is an important question. The demonstrated facts that a large percentage of well-selected chronic cases are relieved and that very many of these have adhesions to a greater or less degree make it evident that these currents do remove adhesions. Undoubtedly it is cases that might be classified as simple catarrhal appendicitis which are cured by high frequency applications. Catarrhal appendicitis, however, as to-day diagnosed, may be only a slight inflammation limited to a portion of the mucous membrane or even involving the entire membrane. There may be simply a catarrhal condition or there may be implication of the entire organ, edema, ulceration and an involvement of the lymphatics. In fact, so many conditions have been, by various authorities, included under the term catarrhal appendicitis that, as a rule, it is safer with due precaution to undertake the electrical treatment in any case of chronic or

recurring appendicitis which is not in such a condition as to place the patient in bed or when there are no signs of the presence of pus or gangrene.

In the year 1903, after having had some success in the treatment of an inflamed prostate with the static wave current, I undertook the treatment of a case of chronic appendicitis by the same method. There had been a slight initial attack which, with occasional recurrence of the symptoms, was sufficient to confine the patient to his bed for a few days. The method of treatment was to place the active electrode, which was a piece of block tin about four inches square, anteriorly over the region of the appendix. Fifteen treatments were given with apparently complete relief of the symptoms and there has been as yet, seven years after, no return of them. During the following year I treated seven cases. One other was apparently a perfect cure. Another patient was relieved for about a year and two experienced some temporary relief. The other cases were complete failures. In the autumn of 1904 I began using high frequency currents as generated by the D'Arsonval apparatus. The first treatment was by autocondensation, passing 250 ma. as registered on a hot wire meter. The following day the case exhibited a marked aggravation of all the local symptoms which were relieved by heavy treatments with *x*-ray, using a hard tube. Two weeks later the same number of ma. was given for four minutes without aggravation and with some relief during the following days. The same treatments were continued, gradually increasing the duration of the applications to twenty minutes until all objective symptoms and tenderness had disappeared. Other cases were treated by this method with varying results, but the failures were more than the cures; and in some instances there was distinct aggravation of the symptoms.

All these treatments were given with the old standard type of the combined D'Arsonval and Oudin apparatus, a Ruhmkorff coil being used to charge the condensers which were two quart sized Leyden jars. The rate of oscillations from such a coil is very low, probably not reaching 100,000 per second. I believe it was the low rate of alternations with perhaps the corresponding greater amplitude accompanying this low rate that caused the aggravation; and it was found necessary to exercise great caution in the beginning of the treatments. With the apparatus and technique I now employ I have yet to witness any aggravation, even when using as high as 1,800 ma. as registered on a hot wire meter, with an application of thirty minutes' duration. It is, therefore, necessary to describe briefly the kind of current and the apparatus employed in the following cases, for it is quite as important that the apparatus used should be constructed on a correct principle as it is to employ a correct technique. The special manifestation of high frequency currents employed for these treatments was described by D'Arsonval during his earlier experiments as derivation currents. The patient, or that part of the body in the electric field, is placed in parallel with the solenoid. In other words the two electrodes placed on the patient are connected to the two ends of the solenoid. More recently this method of application has been extensively written about, mostly by German authorities, under the name thermopenetrating currents. In this article the two terms are used indiscriminately.

I do not know if the different methods of producing a high potential current to charge the condenser make any difference in the condenser discharge, providing the current be of sufficient amperage and voltage. I have never had a static machine that gave a sufficient amount of current, although I have used a machine of sixteen revolving plates, each thirty-six inches in diameter. I do not doubt, however, that a Ruhmkorff coil with a proper interrupter can be successfully used for this purpose. The apparatus I have employed has been of the alternating type, the direct current being converted into an alternating one by a rotary converter. This alternating current passes through a step-up transformer. This high voltage current charges a condenser built up of layers of mica and tinfoil. However, this in itself is not sufficient. The step-up transformer and the condenser must be made so to harmonize that the current shall be perfectly smooth, of very high frequency, and shall give no sensation to the patient other than a comfortable warmth underneath the electrodes. In my judgment the secret of success depends upon the quality and frequency of the current employed; and no one has a right to judge of this treatment unless he has used such a current.

Take as the standard a Leyden jar, pint size, with only a short thick wire to connect the internal and external coatings, giving off 15,000,000 oscillations per second. When we take the square of the surface of the condenser I have employed, together with the solenoid, the oscillations must be at least some millions per second. In my experience the solenoid and condenser which give the best results in autocondensation have not proved most useful in the derivation method of applying these currents, and I cannot urge too strongly the necessity of having the transformer, condenser and coil so tuned that a perfect smoothness of oscillations is produced, of the highest frequency, for derivation or thermopenetrating currents.

During the year 1905 I first treated these appendicitis cases by autocondensation, using 300 to 400 ma., and finally ending with derivation or thermopenetrating currents. Now, however, I do not use autocondensation at any time, but begin at once with thermopenetrating currents. With the apparatus I have used I am able, at all times, to obtain 1,800 ma. with an even discharge; and this amount has been the maximum of amperage I have employed. The technique is very important. I place on the back directly opposite the appendix a sheet of tinfoil four inches in width and eight inches in length. This is carefully pressed against the skin so there is not a wrinkle in it. Over this is a piece of block tin, about two by six inches, which has a solid metallic connection with the rheophore leading from one terminal of the coil. In front, directly over the region of the appendix, is another piece of tinfoil four by four inches. As the current is more concentrated at this point it is not only necessary that the tinfoil should be perfectly smooth but it is best to moisten the skin, preferably with a little soapy water, so as to reduce the resistance. Next to this is placed a piece of block tin, two by two inches, with the solid rheophore connection. If the tinfoil has been carefully adjusted in both instances and there is steady and even pressure to hold them in position, and if the apparatus employed is of perfect construction 1,800 ma. may be passed without causing the slightest inconvenience. In fact the only sensation noticed is a mild warmth, more agreeable than otherwise, underneath the electrodes. If, however, the electrodes have not been well placed, the tinfoil being wrinkled, the contact

not being good between the tinfoil and the block tin, or if the connection between the block tin and the rheophore is imperfect, the burning pain will be so severe that a patient cannot bear it. This is fortunate; for if the current is not immediately turned off there will be destruction of tissue not unlike the destruction in fulguration discharges, which may be painful and a long time healing.

If I should undertake to explain exactly what action takes place by the passage of high frequency currents through an inflamed appendix I should of course be led far into the field of speculation and away from demonstrable facts. However, one observation may throw some light on the subject. It has been known that if a high frequency current is made to traverse a piece of meat and thermometers are placed, one near each electrode and in rather close proximity thereto and one midway between them, the rise of the column of mercury in the middle one, or the one farthest from the electrodes, during the passage of the current, is greater than it is in the ones approximately nearer the electrodes. In order to verify this I undertook three experiments. A piece of beef's liver ten inches in length was utilized for the purpose. Across each end was placed a piece of tinfoil to which the conductors were attached in the same manner as described above. The resistance of the liver proved very great. A certain initial force and spark gap which when given through the abdomen registered on a hot wire meter 1,500 ma. would only register 200 ma. when passed through this piece of liver.

In the first experiment 200 ma. were passed. The bulbs of the thermometers were pressed down well into the substance of the liver and sufficient time was allowed to elapse for the column of mercury to become stationary before the current was turned off. The figures given below in the first two experiments were the records taken every five minutes, the first and last in each line representing those nearest the electrodes.

52 degrees	52 degrees	52 degrees
56 "	58 "	56 "
58 "	62 "	58 "
60 "	64 "	60 "
62 "	66 "	62 "
64 "	68 "	64 "

The second experiment was prepared the same as the first and 250 ma. were passed with the following results:

64 degrees	64 degrees	64 degrees
68 "	70 "	68 "
70 "	74 "	70 "
70 "	74 "	70 "

The third experiment was made in a similar way, only with a stronger current, 1,150 ma. being employed. The apparatus was also of different construction, the energizing force being a Ruhmkorff coil with a mechanical interrupter. The register was taken every two minutes.

53 degrees	53 degrees	53 degrees
56 "	60 "	56 "
59 "	66 "	59 "
62 "	69 "	62 "
65 "	74 "	65 "
68 "	76 "	70 "
70 "	79 "	72 "
73 "	81 "	77 "
75 "	85 "	80 "
76 "	86 "	80 "
78 "	88 "	82 "
79 "	89 "	83 "

If we attempt to examine into the cause of this increased heat midway between the electrodes, a phenomenon contrary to all general laws of transmission of energy, we are forced to admit that we have no sound foundation even for speculation. Some points, however, are well worth considering. Observe that the rise of the column of mercury in all the thermometers, no matter where located, was in proportion to the strength of the current employed. If anything the ratio of increase to the strength of current was greater in the stronger application than it was in the weaker. Another thing noticeable was that the ratio of increase in the thermometer centrally located, and farthest from the point of energy, was greater the stronger the current employed. These facts, however, do not prove whether the increased heat farthest from the electrodes was due to electrolysis or to mechanical causes.

The clinical portion of this paper is based on forty-two cases. These comprise all I have treated and completed from the autumn of 1907 to June, 1910. All were selected as suitable for the treatment. All but seven had been diagnosed by other physicians than myself and operations had been advised more or less strongly. Of these forty-two cases four were complete failures. Every opportunity was given to them and why the treatment failed I cannot say. One thing is noteworthy, and that is that two gave a history of syphilis. There was no aggravation nor amelioration of any of the symptoms except in one case. After a thorough trial the four were dismissed as they had been received. In the one exception mentioned all symptoms would apparently clear up under treatment, but two months after discontinuance all would return. Treatments were again given with the same result and this experience was repeated four times. Six others must go down as failures as they were not cured; but I do not consider that in these cases the treatment had a fair trial. I feel certain a good proportion of these patients could have been cured had they been less skeptical and given the treatment a longer trial. Six were only partial successes. Some were benefited very much, but fell short of that apparently complete cure which characterized the remaining twenty-six.

It is my purpose to report eleven cases with some detail. In their duration, the length of time treatment was required, and their general characteristics, these eleven constitute a fair illustration of all the successful cases. I am quite aware that not a great length of time has elapsed since these cases were discharged as cured, but in two instances only have there been any signs of recurrence of the trouble. Two treatments in one and seven in the other removed the threatening symptoms and there have been no other outbreaks. All these cases were carefully cared for from a medical standpoint. Diet and exercise were carefully regulated, the bowels were kept freely open, and errors of digestion were corrected by medication so far as possible.

Case I.—Mrs. G. A. first consulted me on September 4, 1907. She gave a history of an attack of appendicitis which, during the month of April preceding, had kept her in bed for three weeks. The following two or three months she had been comparatively well. During August she had complained of pains in the abdomen, general lassitude, loss of appetite and weight. There was a well-marked tenderness over the region of the appendix; even slight pressure produced nausea and what she termed dis

tress in the abdomen which would remain during an entire day. There was a dullness reaching from the right iliac fossa upward and to the left. The first treatment was given December 4, of 1,200 ma.; the next on December 7, of 1,400 ma.; and a third December 11, of 1,800 ma. Thereafter treatments were repeated three times a week during the remainder of December and until the 11th of January. Then they were given on January 16, 21, 24, 28, and 31, at which time the patient was discharged. She was seen again on March 1, but as there had been no recurrence of the symptoms she was not treated. In September, 1909, she was still well.

Case II.—Mrs. B., on October 13, 1907, gave a history of three recurrent attacks of appendicitis during the preceding two years. She was treated on October 13, 16, 20, 22, and 30, and three times a week during the month of November. Six treatments were given during the month of December at regular intervals; one treatment a week during the month of January, 1908; one treatment in two weeks during February. She was discharged as cured February 23, and there has been no recurrence of the trouble. In this case 1,800 ma. were given from the first.

Case III.—E. M., first consulted me on October 27, 1907. She was a young lady of 21 having just completed a boarding school education. During the winter previous she had what was diagnosed as an acute attack of appendicitis; an operation was contemplated but was abandoned as recovery was apparently complete. Soon after she began losing weight. She suffered some pain in the abdomen, but, as I am informed, without temperature. From July until October she lost about twenty pounds and, not having been a particularly fleshy girl to start with, she looked extremely emaciated. There was excessive tenderness over the region of the appendix and an area of dullness with an apex pointing upwards and to the right. Treatments were given cautiously, at first twice a week, using not more than 400 or 500 ma., but gradually increasing until November 13, the sixth treatment, when 1,800 ma. were given, this strength of current being continued twice a week until December 3. From this time on treatments were given once a week until January 7, 1909, when she was discharged as cured.

Case IV.—Mrs. J. H. B. first consulted me on January 20, 1908. She had a marked chronic appendicitis, had had two acute attacks, was well aware from what she was suffering and on the advice of her physician was about to have the appendix removed. There was a well-marked dullness in the region of the appendix. She had few other than purely local symptoms. She was treated January 22, 25, 27, and 30. During February six treatments were given at regular intervals, during March three treatments, during April four treatments, during May four treatments, and in June one treatment. She was discharged cured on the 6th day of June. Twelve hundred ma. were passed at the first treatment, but 1,800 ma. were given in all subsequent applications.

Case V.—Mrs. I. W. H. came to me April 6, 1908, with a history of an acute attack of appendicitis two years previous with three slightly recurring attacks, the last one a month previous to her consulting me. There were a number of ill-defined abdominal symptoms with marked tenderness over the region of the appendix. She was treated on April 6 with 1,400 ma., on April 10 with 1,600 ma., on April 13 with 1,800 ma., and every other day until April 27 with 1,800 ma. On this last date there was apparently a slight recurrence and she was ordered to keep quietly in bed for three days. Treatments were again resumed on May 15 with 1,000 ma., followed on May 18 with 1,200 ma., on May 21 with 1,400 ma., on May 23 with 1,600 ma., and on May 28 with 1,800 ma. These treatments were continued at regular intervals three times a week until June 26, when she was apparently well and went away for the summer. I next saw her on the 24th of October, 1908. Although she was apparently perfectly well it was thought best to give a few treatments. Accordingly she was treated on October 24 and 31, and on November 8, 15, and 23, at which time she was dismissed as cured. I have seen the patient from time to time since and she has remained well.

Case VI.—Miss F., I first saw on April 17, 1908. She gave a history of chronic appendicitis and three different surgeons had advised operation. There was marked tenderness over the region of the appendix and the history of shifting, irregular pains of every conceivable kind through the abdomen was the most notable of any case I have ever seen; many of these pains must have been imaginary or greatly exaggerated. She received her first treatment on April 24 with 1,000 ma. This was repeated on April 28 with 1,200 ma.; on May 1 with 1,400 ma.; and on May 4 with 1,800 ma. Treatments were then continued regularly three times a week with the exception of a period from May 23 to May 30, when they were discontinued. From May 30 they were given twice a week until June 22. At this time all local symptoms had disappeared; but the irregular, shifting indescribable, incomprehensible pains in the abdomen continued. She thought she suffered very much less than she did before, but her complaints were many. I have seen this patient since and while there was no local soreness she was still complaining up to September, 1909, at which time a magnetic wave treatment caused almost immediate relief. Whether this result was psychical or not I do not know, but am inclined to believe that it was.

Case VII.—Mrs. L., aged 30, had recently married and while on her wedding journey had been taken sick and was treated for what was diagnosed as malarial fever. She had improved sufficiently to be brought home, being transported from the train to her house in an ambulance. I saw her September 2, 1908, soon after her arrival. The history of the case showed a marked periodicity. My attention was called by the nurse to a constant abdominal pain which had been there from the first. Examination revealed a well-defined case of acute appendicitis, which was at this time rapidly subsiding, although there was still marked dullness in the region of the appendix, and great tenderness and pain on the least pressure. She was kept quiet, with bowels free, but otherwise not much medication was used. She continued to improve and was able to come to the office for treatment on October 2, one month after her arrival in the city. During the month of October she received at regular intervals twelve treatments; the tenderness subsided rapidly, and all symptoms disappeared. Two treatments were given during the month of November, and she was discharged as cured on December 2. The rapid recovery in this case was undoubtedly due to the fact that treatments were begun so soon after the acute symptoms had passed away and resolution was more quickly accomplished.

Case VIII.—Mrs. J., an English woman, gave a history of an indigestion dating back for three years. The first history of any inflammatory condition of the appendix, and diagnosed as such, was in May, 1908, in London. From this attack she apparently recovered. During the early part of September, on a voyage to this country, the symptoms of appendicitis returned. I saw her on the day of her arrival, September 12. There was a well-marked, mildly acute appendicitis. She was put to bed and kept there until September 28, when she was allowed to get up and move around. On October 7 the pain had disappeared, leaving a tenderness such as she said she had after the attack in London; but the digestive disorders had greatly increased. The first treatment was given with only 400 ma. The current strength, however, was rapidly increased so that at the fourth treatment, on October 16, 1,800 ma. were administered. From this time on she was treated three times a week until November 13, when there appeared to be a slight aggravation of the condition which before was apparently subsiding rapidly. Treatments were discontinued until November 28, when only 1000 ma. were administered. On December 4 1200 ma. were given; 1600 on December 8 and 1800 on December 11; after this date they were continued three times a week. On January 4, 1909, there was again a slight relapse which caused me to discontinue treatments until January 7, when they were again resumed with 1000 ma.; on the 9th with 1200 ma.; on the 15th with 1600 ma.; on the 19th with 1800 ma., and continued at 1800 ma. three times a week until February 24. As there were no symptoms of return and the tenderness had disappeared, treatments were discontinued until March 16, when she was again examined and received one treatment. To September, 1909, she had remained well and with great amelioration but not complete relief of the digestive symptoms from which she had complained for more than two years.

Case IX.—Mrs. J., a widow, 62 years of age, first consulted me on October 6, 1908. She had a history of illness dating back a number of years which, according to her, had been diagnosed as inflammation of the liver. There was no history, however, of jaundice. There was a well-marked appendicitis, tenderness, and dullness reaching from the appendix toward the umbilicus. The first treatment was given on October 6, and regular applications were made at the rate of three per week to November 24. There were no untoward symptoms in this case, but a gradual improvement. I last saw her in October, 1909. There were no signs of appendicitis and she has had no recurrence of the periodic attacks of her so-called inflammation of the liver, which, I believe, were recurrent attacks of appendicitis.

Case X.—Miss W. first consulted me October 27, 1908. A woman of 35, she had been failing in health for two years, during which time she had lost weight, being reduced from 160 to 130 pounds. She had been suffering with abdominal distress, which she described as an irregular, abdominal pain, centering on the right side. On examination a very tender spot was found by pressing over the region of the appendix. The pressure caused nausea and faintness. She had been aware of the soreness in the region of the appendix for more than a year, but had not had any acute attack or other diagnosis of appendicitis. The first treatment of thermopenetrating currents was given on the 27th of October. This was repeated on October 30. During the month of November twelve treatments were given at regular intervals. During the month of December twelve treatments were given at regular intervals. Five more were given during January, 1909, two during February, the last one February 21st, at which time she was discharged cured and has had no return of the symptoms.

An examination two weeks after beginning the treatment showed a marked reduction of the sensitiveness to pressure. There was but slight dullness in the region at any time. In June, 1909, all the abdominal symptoms had disappeared and she had regained her former weight. Eighteen hundred ma. were given from the first.

Case XI.—Mr. E. A. M., 72 years of age, had been in feeble health for two or three years. I first saw him May 10, 1909. He was suffering with a slight attack of acute appendicitis and was kept quietly in bed with ice packs over the region of the appendix. Electrical treatments were not begun until June 3. At this time he was in his country home, where there was an alternating current on the street mains and a portable apparatus was employed. During the month of June he received, at regular intervals, fourteen treatments, and during July, also, at regular intervals, fourteen treatments. On July 11 an unfortunate family incident completely prostrated him and from this he did not recover for two weeks. This prostration seemed to aggravate the appendicitis very much. During August he was treated five times. He had now improved so much that he was allowed to go away on a large sailing yacht. On September 23 he returned greatly improved in general health, but the region of the appendix was still sensitive on pressure and also slightly painful. During October he received fourteen treatments at regular intervals; during November ten treatments at regular intervals, and during December two treatments, being discharged as cured on December 5th. Only 1400 ma. were employed in this case as the portable apparatus was incapable of giving more.

40 East Forty-first Street.

THE FUTURE OF PSYCHOTHERAPY.*

By THEOPHIL KLINGMANN, Ph.C., M.D.,

ANN ARBOR, MICHIGAN.

To many physicians psychotherapy even to-day appears quite unscientific and unworthy of the interest of a natural philosopher. But I ask your kind attention for a moment that I may point out to you that this verdict is unjust or erroneous since this method of treatment has been put upon a sound basis. In the first place, you will remember that psychotherapy is not a modern therapeutic measure, and I refer you to the instructive work of Löwenfeld[1] where it is shown that most of the methods employed in primitive and ancient medicine were of a psychotherapeutic nature, and even after other remedial agents were found, psychotherapeutic treatment has never disappeared from this or that branch of medicine, and I dare say that all who practise medicine apply the psychotherapeutic method, even though unconsciously. Without our intention an independent factor enters into the activity of every remedial agent from the patient's as well as the physician's psychic disposition. This may be in a favorable sense, but often also in an inhibitory sense, and the failure of some

*Read at the forty-fifth annual meeting of the Michigan State Medical Society, Bay City, Mich., Sept. 28-29, 1910.

of our remedies can be ascribed to the disturbing influences of these moments. Further I refer you to the well-known fact of which we are all convinced by personal experience that certain maladies, particularly the psychoneuroses, are more accessible to psychic influence than any other medication; it is a dictum of old physicians that these diseases cannot be cured by drugs.

"It is the mind that maketh good or ill, that maketh wretch or happy, rich or poor." [2]

I am well aware of the fact that the physical often acts on the moral, but I believe it is more adequate and frequently more correct to influence the moral with the moral.

We no longer limit the application of this principle to our usual consolations with which we are so generous to our patients and through which we transfer them into a state of credulous expectation in which the principle of what we have termed "suggestion" is involved, and which, in brief, is only another name for the power of ideas, and the ideas and conduct of one person influencing the belief and conduct of another person. So can the conscious mind of a human being bring its own transliminal into the control of its own organism. The objective consciousness can suggest to its own subjective consciousness, hence the term autosuggestion. In the practical application of this principle in the treatment of hysteria and other psychoneuroses, I recall with much pleasure the numerous splendid and prompt results obtained in relieving patients suffering for many months and even years from deafness, blindness, loss of speech, paralysis of the extremities,and those who had become bedridden by agonizing pain. On the other hand, I have been sadly disappointed in my expectations that a permanent cure had been effected. Many of these cases are apparently well for three or four months and even longer during this time the principles of autosuggestion were active, or perhaps the occasional reassurance, reaching the patient through correspondence, prolonged the effect of the treatment, but eventually, when the last connection was severed, I was forced to acknowledge that the treatment had accomplished nothing. The same symptoms reappeared, or I found that I had removed one symptom only to make room for another. I was not spared the depressing impression of fruitless efforts and the disappointment to the patient and relatives. Nevertheless, I set forth to explain these untoward results, and found much consolation in the excellent conclusions drawn by Freud[3] that the suggestion technique does not concern itself about the origin, force, and significance of the morbid symptoms, but suppresses the causative factor by putting on something, to wit, the suggestion, which it expects will be strong enough to prevent the pathogenic idea from expression. It is like the hypodermatic injection of morphine to relieve the pain of an organic disease without further investigation or treatment of the disease; as the action of the drug disappears and the pain returns, so does suggestion crumble off and then the symptom or one replacing it reappears. It is therefore clear that this method of treatment is based neither upon sound medicine nor sound psychology. This is the *modus curandi* of Christian and mental science, metaphysical healing, faith and prayer cures, osteopathy, and other delusions.

I have long since given up the technique of suggestion, and with it hypnosis, which is suggestion to the subconscious mind, suggestion in a larger dose concealing from us the psychic mechanism and increasing the patient's resistance with which he adheres to the disease and strives against a favorable termination of his malady. The only value in hypnosis is in connection with the psychoanalytic technique in gaining access to the subconscious mind with the view of divulging the pathological idea, the causative factor of the disorder. One objection to the practical application of this method is that not all patients are subject to hypnosis and, furthermore, it is not now necessary to subject our patients to the hypnotic state since Freud[4] has explained the formation and significance of dreams; and as Brill[5] puts it, "the dream is not a senseless jumble, but a perfect mechanism, and when analyzed is found to contain the fulfillment of a wish; it always treats of the inmost thoughts of personality, and for that reason gives us the best access to the unconscious; no psychoanalysis is complete or possible without the analysis of dreams; the dream not only helps us to interpret symptoms, but is often an invaluable instrument in diagnosis and treatment; the causative factors of many neuroses are extremely vague and usually unconscious to the patient, and it is by means of the dream that the underlying etiological factors are disclosed."

Perhaps from personal experience we fully realize that to forget is a part of human nature, and that we are most apt to forget painful or disagreeable impressions. The individual strives to rid himself of the unbearable, either by adjusting the situation, or by directly crowding it out of the mind. In this desperate effort to forget he represses it. This repressed material is pushed into the unconscious and there remains in a dormant state. This repression complex is not always successful and a splitting of consciousness may result. When this takes place, through the strife of the repressed complex for manifestation, a psychic conflict occurs with a resulting psychosis or neurosis. No matter how the repressed comes to the surface, whether in the form of dreams or in psychoneurotic symptoms, it is always distorted and is not recognized by the individual. These distorted manifestations of the dream content seem absurd and incoherent, but by psychoanalysis one can readily translate them into latent thoughts which always show the fulfillment of a wish.

As Freud has shown, dreams are definite psychological mechanisms. Their manifestation, though distorted, has a definite meaning and is the expression of a former mental occurrence, a product of the unconscious, and hence affords an easy access to the mechanism of the psychoneuroses. Through this Freud overcame the difficulties of hypnosis which was so essential in the cathartic method of broadening the patient's consciousness, and he adopted a new procedure which he called the psychoanalytic method. In the application of this method one finds that during the waking state patients can give little or no information with reference to the first motive of the symptoms in question, partially because the discussions are disagreeable to the patients, but mainly because they cannot be recalled and they have no memory of the occasions causing the pathological phenomenon. Here the accidental moments play an important part and frequently that which evokes the syndrome. The most varied symptoms, often regarded as idiopathic attainments, stand in close connection with the causal moment. To such causal moments one can refer neuralgias, the various sensory disturbances,

contractures, and paralyses of every description often of years' duration. To bring these causal moments into the field of consciousness one meets with a great deal of resistance, but by urging and reassuring the patients that by concentrating their attention and repeating the thoughts that would occur to them will awaken forgotten impressions, they finally recall the pathogenic ideas. Without going any further into the theories upon which this method is based, or Freud's conception of the psychoneuroses[6] for which I have neither time nor space, I must refer you to the writing of Freud to which I have already alluded. Let me cite an example to illustrate this method of treatment and other points mentioned above.

The patient was a young married woman, 27 years old, of an apparently cheerful and happy disposition. She was well educated and spent some time in teaching elocution and music. During her six years of married life she states that she has been happy. There are no children and she has never been pregnant. When I first saw her she complained of pain in the ovarian regions, in the spine, and in the lower extremities. Physical exertion, especially walking, is painful and fatiguing, and for two years she has been an invalid, which she attributes to disease of the female organs. She cannot recall the beginning of this trouble, but states that it has been more pronounced for two and a half years. The family history is good, and aside from the ordinary diseases of childhood she has never had any serious illness. At the age of 18 she became languid and was easily exhausted. She was married at 21. The physical examination revealed nothing of interest. The neural examination showed the following conditions: The right conjunctiva was anesthetic, with an analgesia extending over the entire left side of the body without tactile impairment, with marked inframammary tenderness on the left side, no tenderness on the right. Light pressure on the left side of the spine from the second thoracic vertebra to the sacrum was painful. Pressure in the ovarian regions caused pain, more marked on the right side. Plantar irritation of the right foot caused plantar flexion of the toes on the left side but not on the right. These are interesting hysterical manifestations which are significant. So far the beginning of the trouble has been very indefinite. The fatigue and early exhaustion at 18 gives us some clue that the causative factor might have existed then. She could not recall that she had pain at that time. I began the treatment by putting the patient in complete isolation in bed. I found at my daily visits that the pain in her back and extremities absorbed her whole attention. After two weeks of rest and complete isolation I began active treatment for two hours each day. The patient was told to close her eyes and concentrate her mind upon the surroundings and associations of her childhood. Among other things she stated that when a little girl of five or six years of age, she was obliged to hold her side when running with other girls and was unable to keep up with her companions. During these recitals she was not in a hypnotic state. The second time I saw the patient she related that during her girlhood she was obliged to work very hard, her mother being a very ambitious woman and in very moderate circumstances. By this she was frequently detained from society events in which her associates were allowed to participate. Here came a series of disappointments of this character, but which were concealed by the thought of a new home to which end her father and mother were striving. I questioned her regarding the character of the work she was obliged to do and I found that it required a great deal of stooping. In this she recalled that at the age of 13 or 14 she had pain in her back and sides, also that she was taken to a physician who said that she had ovarian trouble, and advised her mother that she must not permit her to ride horseback, which was her favorite sport. She stated that she was extremely fond of horses. In the course of this treatment it developed that it was not the pleasure of riding and her fondness of the equine, but altogether the particular associations which surrounded these jaunts. She explained that her constant companions consisted of a party of two young men and a girl friend, all of whom were somewhat older than she. During this time she became very much infatuated with one of the young men, who gave most of his attention to her girl friend. A disagreement arose between the two girls, the occasion of which caused a "breaking up" of the party, and thereafter the excursions were taken in pairs, much against the wish of her parents, particularly the father; owing to the advice of her physician she was obliged to give up these excursions. However, the young man was still a frequent caller at her home. Knowing the opposition of her father she arranged to meet her friend in the arbor. About this time she received some indefinite information concerning the calamity which had befallen her former girl friend at the hands of this young man. Finally one day while lying in the hammock, deeply absorbed with thoughts of her friend's misfortune, she was surprised by the young man, who had been hiding in the arbor, and through her sudden attempt to rise the hammock broke down and, with it, she fell to the ground, the fall causing her considerable pain in the lower part of the spine and lower extremities. It was some time before she recovered from this pain, but she did not think that she was seriously hurt. While much disappointed that this happiness should terminate thus, it caused her no great worry and it soon passed into obscurity. All this the patient related with the utmost calmness. When I asked her why she did not tell me this before, she stated that this had not occurred to her since the closing of the incident, until I suggested to her that she review her early life and had given her a starting-point which brought out this train of thought. While I realized that I had succeeded in broadening the patient's consciousness at this stage of the psychic treatment, I had failed in gaining access to the deeper strata of consciousness retaining the pathogenic idea during this period of treatment. The patient never failed to inform me that she was no better and was having the same pain as before. Nevertheless, I continued my analysis. A number of subsequent treatments were unsuccessful. I therefore decided to suggest a number of words which occurred to me during the patient's previous conversation, to her already broadened field of consciousness, requesting her to unfailingly inform me of what came to her mind or passed through her memory. Upon suggesting the word "accident" there followed a long pause (ten seconds), but eventually came this: "I recall a dream which occurred to me frequently before I was married and even during the first period of my married life in which I saw my father seriously injured, and at one time saw him dead in one of these dreams. I was driving a spirited horse (the only kind I cared to

drive), my father was by my side the horse ran away, my father was seriously injured. I was unhurt, gained control of the horse, and drove away alone." She recalled nothing else. With this a new path was opened, the content of which I now gradually brought out. I proceeded with my analysis by suggesting the word "crash." At this moment the patient's face became flushed, tears came to her eyes, she did not speak for several minutes, but finally asked me to discontinue the treatment, as the pain in her back and lower extremities was unbearable; to this I immediately consented. I felt already sure that my suggestion, this lapse of speech, and the other manifestations were either directly or indirectly associated with the pathogenic idea and the psychoneurotic symptom which I had reached through a new path whose portal was the dream. From the foregoing it was also clear to me that the dreams with reference to her father were the fulfillment of a repressed wish representing the latent thoughts of a conscious life. This became more apparent as the analysis proceeded. The next time I saw my patient she stated that the last treatment brought back to her memory an early love affair which had completely disappeared from her mind, also that she was not nearly so well. During the next treatment she related with much emotion the *affaire d'amour* alluded to above. She was at the time of this occurrence between 16 and 17 years of age. Among other things she stated that her association with this young man was most agreeable and she was positive that this was mutual, but her father did not look upon it favorably, and she met with much opposition from that source. Disregarding her father's wish, however, she persisted, fully realizing that at some time, and possibly soon, the happy affair would terminate. In spite of this conviction she was enthusiastic in this affair. She related that on one occasion her lover took her for a drive. It was a dark night and she was driving as usual on these excursions. Through a sudden leap of the spirited horse and the darkness of the night she lost control, the vehicle was overturned, and she was thrown into the ditch, falling upon her back but not being seriously injured, although she had considerable pain in her back and lower extremities. While the young man succeeded in controlling the horse and rearranging the disruption, she had gotten out of the embarrassing situation and was ready to return home. During the homeward journey she apprehended her father's reproach and that this accident would be the beginning of the end and possibly the termination of it all. This was soon fully realized. For a number of days she was unable to be about on account of the pain in her side and lower extremities. After returning home on the evening of the accident she said to her mother: "We have had a crash." In reply the mother said: "Have you broken up?" This was the first time that the word "crash" occurred in her conversation which, as you remember, proved to be the key to the innermost portal of the new passageway found through the dream leading to the deeper strata where the pathogenic idea was stored. Gradually the patient came to the realization of her previous apprehensions and, as she expressed it, "I was very unhappy, to say the least, and so was the young man; I now believe that I have never gotten over it." There were no opportunities to explain or reconsider, there was but one alternative and that was to forget. A conflict began between the happiness which she had and the sad condition in which she found herself after the storm was over. This struggle resulted in a process of repression (Freud's idea of repression) and eventually was transformed into an hysterical symptom by conversion. When she came under my care there was already a complete isolation from her consciousness of the presentation referring to this affair.

The foregoing confession brought no relief to the patient, in fact, she told me that the pain was almost unbearable. I proceeded on the assumption that she was still in sympathy with her friend. I decided to put a direct question, which brought out much emotion but no response. She neither denied nor confirmed it. By urging her she stated: "I cannot deny nor confirm it. Your suggestion brings invariably to my mind's eye a picture which I recognize as my husband." The pathogenic idea was there constantly inhibited by the psychic censor. Not until I was able to overcome this resistance, which opposed the pathogenic idea from becoming conscious, was the cure effected. After this period of abreaction the patient's condition showed immediate improvement both somatically and psychically, and within a short period she was well and happy.

The conclusion one may draw from all these experiences is that the pathogenic moments with all the concomitant circumstances are fully retained in memory, even when they seem forgotten and when patients are unable to recall them. One may assume that these first pains in early childhood were due to a slight myositis coming on only during violent muscular exertion. The second attack had both a physical and psychical basis of a sexual nature and was the model for the later hysterical imitation occurring after the fatal ride, assuming identical proportions and distribution. One sees in this a perfect mechanism, so in the dream the mental picture of her father who was the obstacle. The perfect management of the runaway horse, and she unhurt, was the expressed wish of a successful attainment of that which she most desired after removing the obstacle.

I dare say that the old saying, "there is method in madness," has been fully realized. One knows now that every morbid perception and every pathogenic manifestation has a definite meaning.

The theories of Jung and Freud have succeeded in revolutionizing the methods of diagnosis and treatment of psychoneuroses and have placed psychotherapy upon a sound basis. A wide field has been opened through this line of research, laboratories of applied psychology, educational dispensaries, psychological clinics and hospitals have been established at the best schools abroad and in this country. One needs only to review the recorded achievements of this science to foresee the wonderful posibilities of the future.

Opsonic Treatment of Septic Conditions.—In a report made last year by Mr. E. M. Corner it is stated that the vaccine treatment of septic conditions at St. Thomas' Hospital, London, has been disappointing. In the case of carbuncle the stay in hospital was not shortened by the vaccine treatment, and the results in other septic conditions were equally indifferent.

DUODENITIS.

By M. GROSS, M.D.,

NEW YORK.

It can be easily understood that affections of the duodenum have been up to the present time *terra incognita,* but by means of the duodenal tube that I have devised* it is now possible to reach the duodenum direct, and it is now merely a question of time when one will be able to include this part of the digestive tract, its normal and abnormal functions in the range of investigation. This tube is merely a prolongation of the ordinary stomach tube. The patient swallows a little silver ball which is attached at the end of the tube; then a position on the right side is assumed and the ball gravitates toward the antrum pylori, drawing the tube with it. The propulsion mechanism of the gastroduodenal part then causes it to progress through the pylorus and into the duodenum. The introduction of the tube is easily and rapidly effected, and within half an hour, or at the most one hour, it is possible to obtain the characteristic contents of the duodenum by means of aspiration.

After extensive burns of the skin, the type known as fulminating duodenitis is shown by the inflammation of the duodenum, and the strongly hyperemic mucosa here displays a tendency rapidly to ulcerate and perforate. Clinically there will be found pain in the duodenal region and icterus, often enough also hematemesis or sanguineous feces. Hunter assumes that this form of duodenitis results from the excretion through the bile of an irritating substance taken up either from decomposed blood at the burned places or from the wound itself. If this theory be correct the possibility suggests itself that other forms of duodenitis may develop even without burns as a continuation of the inflammation of the bile ducts, constituting a mode of spreading different from that which is usually observed.

Another well-observed form of duodenitis consists in inflammation of the duodenal mucosa following duodenal ulcer. We are indebted to Moynihan, Mayo, Chvostek, John Munro, and E. A. Codman, of Boston, for a good insight into these affections. Through them we have learned the true course and fate of a duodenal ulcer as observed upon the operating table; furthermore that duodenal ulcers, which are generally situated at the pylorus, are occasionally not only surrounded by tissues subject to more or less extensive inflammatory reaction and manifest themselves at this stage by well characterized symptoms, but also that remoter parts of the duodenal mucosa may become involved in the inflammatory process by contiguity, constituting in fact a form of duodenitis so extensive that secondary icterus may develop.

I wish to take this occasion to interpolate the following: The incontestable fact that I have nearly always been able to aspirate gastric contents, mixed with duodenal juice immediately after the pyloric ring had been passed, points to the probability that this part of the duodenum, approximately corresponding to the *pars horizontalis superior,* is a kind of transition link in the chain of the mechanism of digestion. In this part the chyme coming from the stomach rests for a very short while, but long enough to be impregnated with duodenal contents, after which it will flow rapidly toward the jejunum in a thin stream, followed possibly, owing to direct irritation of the rapidly traversing contents upon the common duct, by an extra wave of hepatopancreatic juice. Frequent radiographic findings confirm these observations.

Codman's theory, therefore, is not likely to become generalized, although in some cases the dragging, weighted mesentery may exercise such a pressure upon the *pars duodenalis horizontalis inferior* as to cause after some time a distention of the portion behind, and regurgitation of the caustic juice may produce an irritation of the first part of the duodenum. But regurgitation and cauterization alone cannot be regarded as the exclusive cause of a duodenal ulcer, because, as was stated above, there is usually also in normal conditions regurgitated duodenal contents at a distance of 8-10 cm. above the common duct. The same causes, partly unknown as they are, to which the origination of gastric ulcer is attributed, may perhaps be held responsible, too, for the causation of duodenal ulcer. Further investigation in this respect may possibly lead to more definite results.

The most frequently and least understood form of duodenitis is the one which follows as a secondary affection after various gastric disorders, and it is this form of which I will here report a case.

G. D., clerk, 23 years old, single, of regular habits, with good family history, with a personal history of scarlet fever when a little child, has suffered from constipation for a number of years, which, however, never gave rise to special complaints. A year ago he first experienced from time to time an undefined, dull sensation in the region of the right hypochondrium; "he could feel his duodenum," but never had direct pains at this place. In the last six weeks the trouble became more constant without, however, giving rise to greater trouble than before. In the dorsal position he was entirely free from this sensation, while lateral position, especially on his left side, caused it to reappear; so did deep respirations. Patient also complained of great general debility and lassitude from the very first. Appetite good; regular daily evacuations latterly. Examination shows a generally asthenic habitus (Stiller), very slight yellowish discoloration of the skin, especially of the soleræ. Lungs free; at the cardiac apex there is a rough first sound; no albumen or sugar in the urine, but there is biliary pigment. *Abdomen.*—The upper part is somewhat sunk in. Splashing sound two hours after breakfast distinct in the umbilical region. Insufflation shows the stomach in vertical position and slightly ptotic. Spleen not palpable. The liver, which can be felt distinctly, protrudes about 1½ fingers beyond the costal margin, is somewhat hard, smooth and absolutely devoid of sensibility. Gall bladder impalpable, nor is there any sensibility at the place where this organ is normally situated. The duodenum itself cannot be felt, and pressure upon it in the region of the *lobus quadratus* of the liver, but to the left of the gall-bladder and a little deeper, creates no painful but a rather unpleasant impression. This spot is the one identified by the patient as the place where he experiences the spontaneous sensation complained of. Stomach in fasting condition. No splashing sound. About 15 c.c. of a distinctly greenish yellow viscous, turbid fluid are obtained by means of the stomach tube. Congo, dirty gray

Journal of the American Medical Association, April 23, 1910.

coloration. Günsburg, negative. Lactic acid, negative. Microscopic, thin mucous striæ, apparently originating from the stomach, interspersed with epithelia and fragments. Lugol, negative. No yeast cells. Gastric lavage only yielded a limpid fluid which at first had a greenish yellow tint; no food remnants. *Ewald.*—The well emulsified gastric contents show no visible mucus, but filter with difficulty. A larger quantity of it was obtained than could be expected one hour after the test breakfast. There was also a slight degree of alimentary hypersecretion, judging from the distribution of the solids and the liquids after standing. Congo +, pepsin +, free hydrochloric acid 30. T. A. 60. No special features microscopically. Stool, after mixed diet, of normal consistency, light brown, of acid reaction and of slightly pungent odor. Microscopically, quite a number of enveloped and free starch granules, heaps of bacteria stained blue with lugol, rods and cocci. *Duodenal examination.*—Patient was instructed to take a light breakfast consisting of milk, one egg and toast at 7 o'clock in the morning of the day of examination and at 2 o'clock in the afternoon of the same day a glass of milk half diluted with water. At 2:40 the duodenal tube was quickly swallowed. First aspiration at 2:40, 50 cm. from the teeth (stomach); second aspiration at 3:10, 66 cm. (mixture of gastric and duodenal contents); third aspiration at 3:30, 68 cm. (duodenal contents).

Chemical examination of duodenal contents made by Dr. Ofele, and their deviation from the normal, corroborate the diagnosis of "duodenitis catarrhalis" after the disturbances of the buccal and gastric digestion have been established. This is perfectly possible in the present case by a thorough examination of the gastric contents. It seems that the stomach has tried for a considerable time to compensate for some defect in the manner of eating by prolonging the amylolytic period. In the course of time this has led to two further defects which are distinctly expressed in the gastric contents. In the first place the expulsion musculature of the stomach is in a state of atony owing to diminished use and a prolonged state of fulness. In the second place, the stagnant gastric contents have passed into acid fermentation and the zymotic germs exercise an infectious and irritating effect from one meal to the other, because the stomach is never sufficiently evacuated and homogeneously mixed with hydrochloric acid.

As demonstrated by the gastric contents, there was premature regurgitation (?) of duodenal contents, although normal regurgitation corresponds to the ingested test meal (very fat milk) toward the end of the first hour. In the duodenum there has been a normal flow (in a chemical sense) of secretion, the proportion of dry substance to ash of the gastric contents being 4.04:0.20 and 1.85:0.18, which means about 5 per cent. and 10 per cent. For the duodenal contents the figures are 1.19:0.59, or about 50 per cent. The normal proportion is 1.5:0.75, or again 50 per cent. The dilution in the stomach and also in its continuation in the duodenum was exaggerated owing to excessive flow of gastric juice (excited by the fermenting masses). For this reason the specific gravity sank to 1.0053. The significance of this reduction becomes more apparent when we consider that the contents were taken after only one hour and twenty minutes, the normal figure for that time being about 1.007-1.008, and sinking to 1.006 only at the end of the second hour. The total chlorides were 0.425 per cent., which very closely corresponds to the normal average of 0.42 per cent.

Against these relatively normal results of the general analysis there stand those of the special analysis for catarrhal impairment of the duodenal ingestion. Above all the test for trypsin showed that in a 5 per cent dilution of the chyme, casein was digested but poorly, and then at once to abiuretic products. According to previous examinations, this would approximately correspond to a 1 per cent dilution of normal duodenal contents, whereas the latter in such an attenuation would digest the entire casein into albumosis and peptons, but not at once into abiuretic products. At this period of digestion steapsin should be abundant, whereas it was only just distinctly present. On the other hand globulins and related substances carried along with them were absent, nor was it possible to precipitate with acetic acid any dissolved mucins which, in the normal average, yield about 5 per cent volume. Mucins (originating from the gall bladder) are precipitated in the presence of zymic acids and syntonines cannot remain in solution in the presence of insufficient, loosely bound hydrochloric acid (in this case, 0.066 per cent.; normal average, 0.2 per cent.) and it should be noted that a lower figure than 0.15 per cent. or a higher figure than 0.3 per cent. has never been found. In an organ like the duodenum, in which strongly acid (normal gastric contents) and strongly alkaline (bile-pancreatic juice) substances are being mixed, a sticky solution of mucins and syntonines is a natural protection. In the present case this was absent. The microscope revealed the fact that the voluntary centrifugal sediment consisted of mucus which had been torn down in the duodenum and there got clotted together with biliary substances which were dragged along in the process. When such mucous clots are found and when it is possible to demonstrate them as mucous by chemical means (solubility and precipitability) and at the same time to prove the origin of these mucous clots, one can speak of a catarrhal affection at the place of origin. This proof has here been furnished in the demonstration of the presence of duodenal catarrh.

There was only 0.30 per cent of Purdy's albumen (albuminous substances precipitable with acetic and potassium ferrocyanide), as against the normal figure of 0.5 per cent., but this difference need not be taken into special consideration. The total precipitation of picric acid would yield about 1.0 per cent., as against the normal figure of 2.5 per cent., so that the average products of albuminous disintegration are considerably diminished. Again, the nitrogen of the amino acids amounted only to 0.014 per cent. instead of the normal average of 0.040 per cent. Thus we can see that the normal process of digestion in the duodenum is considerably weakened, although, as was stated above, the flow of the secretions must have been normal. From this it follows that the physiologic value of the pancreatico-hiliary mixture has been decreased to an unusual extent during and after its flow into the duodenum. This again corresponds to catarrhal manifestations in the duodenum with a corresponding secondary deterioration of the biological fluids in contact therewith.

Immediately after the last aspiration a duodenal lavage was made with 300 c.c. of warm natural Karlsbad Sprudel, which was easily and rapidly done by means of a funnel attached at the top of

the tube. Subsequent lowering of the funnel, as well as aspiration, brought forth no further fluid, showing that the entire quantity had slowly passed into the jejunum. The tube was then withdrawn to the mark of 50 and again aspirated, by which procedure only small quantities of a mucous and milky substance could be obtained. Immediately after the duodenal lavage the patient felt extremely well. On the second day following another duodenal lavage was given similar to the first one. Icterus was apparently less. On the following day the patient had to leave town, but sent word to say that he felt very well, indeed, better than during the last few weeks.

Rosenheim has said that the only possibility of diagnosing duodenitis was the presence of icterus as a sign of inflammation of the duodenal mucosa, and he has also mentioned as a much less dependable symptom painfulness of the abdomen restricted to the right hypochondrium and increased on pressure, adding that in the latter case the diagnostic probability would point rather to an affection of the gall bladder. Other investigators do not admit that duodenitis can be diagnosed at all and can only be supposed to exist in a few cases.

In our case the following facts stand out clearly: 1. The slight icterus which was never absent in any of the attacks. According to Marsch, icterus is here caused by swelling of the mucous membrane. However, icterus is of diagnostic value only if other causes, such as affections of the liver, the biliary ducts, the gall bladder and general affections, can be ruled out. 2. The sensation was distinctly restricted to the duodenal region; on the other hand there was pronounced insensibility of the ptotic liver and of the gall-bladder region of the liver. 3. The pronounced rapid debility which occurred from the very first after each attack. Here the idea might suggest itself of an alteration or entire elimination of a "specific" function of the duodenum, because icterus following affections of the liver, in which lassitude is also a common sign, is not so clearly pronounced in the former condition. 4. The simultaneous affection of the stomach (slight gastritis, atony, fermentation, etc.). 5. The findings in regard to the duodenal contents. 6. The striking success of duodenal lavage in improving the icterus and producing an almost instantaneous feeling of well being.

Therapy.—The patient was instructed to masticate slowly, to partake of only three meals a day, and to rest, if possible, for half an hour after each meal. A mixed non-irritating diet was ordered, special attention to be given to the proper cooking of the cereals, to the carbohydrates, and to white meats. The patient was ordered to take cold daily sponge baths, short walks, etc., and to wear an abdominal bandage. He was given a few gastric lavages with small quantities (150 c.c.) of water at alternating temperatures, duodenal lavage until the complete disappearance of icterus, and was ordered to take a glass of warm Karlsbad Sprudel an hour before breakfast.

From the manner in which the duodenal tube can be employed according to the description here given, it will be seen that this important means of investigating pathological conditions is easily accessible to the general practitioner, as the entire proceeding occupies rather less than an hour. If the phases of the examination are arranged as described, an hour in the afternoon can be utilized for obtaining the duodenal contents.

GASTRIC ROENTGENOLOGY.*

By E. H. SKINNER, M.D.,

KANSAS CITY, MO.

In presenting any new method of diagnosis there is always more or less hesitancy. There are so many laboratory aids to diagnosis offered to the general practitioner that he begins to feel like a medical clearing-house. And it is true that the general practitioner is the man who looks over diagnostic acids and therapeutic measures to clear the field of those which do not possess merit. It is my humble endeavor, in a few words, to bring to your notice the *x*-ray method of gastrointestinal diagnosis.

The successful treatment of gastric pathology depends upon an early, reliable diagnosis. Surgical technique has advanced beyond diagnostic ability in this as in other fields of medical effort. It may be ventured to remark that there are more present who are familiar, even expert, in the principles of gastric surgery than in gastric diagnosis. Any method, therefore, which may aid or stimulate us in gastric diagnosis merits our attention and study.

The use of the *x*-ray in gastrointestinal diagnosis practically dates from the work of Prof. H. Rieder of the University of Munich in 1904. He published his classical studies in stomach pathology by means of fluoroscoping the stomach *in vivo* after the ingestion of a wheat pudding containing 40 to 60 grams of bismuth salts. At the present day no more satisfactory bismuth meal is offered, but the improvements in fluoroscopic apparatus have been interesting.

Just a few words regarding apparatus and protection of operator and patient. The apparatus necessary consists of a freely movable light tight box, lined with material opaque to the *x*-ray, in which the *x*-ray tube is placed. The box should be fitted with a diaphragm, the size of which may be varied at will. The fluorescent screen should be hung so that it will also be freely movable. The patient is preferably examined in the standing ventro-dorsal position, *i.e.* the fluorescent screen against the abdomen of the patient and the patient's back opposed to the box containing the *x*-ray tube.

The peculiar superiority of fluoroscopy over radiography depends on the ability to study the peristalsis and surgical anatomy of the alimentary tract. One may study the physiological or pathological conditions which influence the position and relations of the esophagus, stomach, and intestines with reference to the adjacent organs and bony skeleton; the anchorage of the stomach and intestines, either normal or influenced by adhesions; the disposal of food in the gastrointestinal tract; pathological filling defects and abnormalities of contour as presented by alterations in the tissues or interference with muscular function of the gastrointestinal tract.

Flouoroscopic Technique.—Esophagus: The patient is placed in the right anterior oblique position and offered a small bismuth capsule. When the current is turned on he is instructed to swallow. The route and rate of the capsule in the esophagus is noted until it reaches and passes through the cardiac orifice of the stomach. Succeeding larger types of capsule are then offered and their course noted. By this means we are able to determine the location and lumen of an esophageal stricture. The capsules do not always find the orifice of a diverticu-

*Report from the Kansas City X-Ray Laboratory.

lum; therefore we employ the bismuth paste (about a level teaspoonful of bismuth carbonate and sugar of milk, half and half). This is swallowed at the suggestion of the operator after the *x*-ray is turned on. The use of bismuth and water (2 drachms of bismuth to 2 or 3 ounces of water) is then employed. By carefully noting the passage of the paste and the water mixture one can determine the presence of esophageal strictures, diverticula, abnormalities due to adhesions, cardiospasm, dilatations, pleuritic tugs, esophageo-bronchial fistulas, carcinomatous filling defects and alterations of outline, and pressure of aneurysms or tumors upon the esophagus. The description of the fluoroscopic symptomatology of each of these conditions is worthy of a separate descriptive paper.

Stomach: Succeeding the fluoroscopy of the esophagus by these simple measures, we instruct the patient to slowly eat 10 or 12 ounces of bismuth porridge. (a) Pyloric stenosis, fluoroscopic symptoms: 1. Dilatation of the stomach, both longitudinally and transversely. 2. Antiperistaltic waves running from the pylorus to the greater curvature. 3. Interference with the emptying of the stomach, the exit of food being delayed 18 to 48 hours. Suspicious symptoms which should be noted are: More or less degree of distention of the stomach, weakened peristalsis, food delayed in exit 12 to 24 hours, adhesions of the pyloric area, which produce a fixed pylorus, pyloric filling defects, absence of any peristalsis at the pylorus, the wave running only from the greater curvature to the prepyloric area. Pyloric stenosis, whether produced by infiltrations and cicatrices about an ulcer or carcinoma, would produce almost identical symptoms. The differentiation can be determined by the stomach analysis, case history, and subjective symptoms.

(b) Carcinoma: 1. Irregular filling defects in the outline of the stomach wall. 2. Abnormal peristalsis, there being no wave at the site of the filling defect; or, if the carcinoma involves the pylorus, antiperistaltic waves are seen. 3. Hourglass contraction where there is involvement of the middle portion of the stomach. The bismuth meal or water may be seen trickling through the narrowed lumen. 4. Adhesions of the stomach to adjacent organs, due to perigastric inflammation. 5. The lumen of the stomach is usually much smaller than normal, excepting where the carcinoma involves the pylorus, one may have a dilatation.

(c) Gastric ulcer: 1. Filling defects, which are not as irregular in outline as in carcinoma, the filling defect being due more to an irritation of the muscular action than to irregular outlines of mass changes in the stomach wall. This interference with the peristalsis in ulcers of the lesser or greater curvature is interesting. Where the ulcer involves the pylorus one has the additional symptoms previously noted when there is interference with the exit of the food.

(e) Gastroptosis: The outlines of the stomach are so exactly recorded by the bismuth shadows that one can easily determine the relation of the lesser and greater curvature to the umbilicus and bony skeleton.

It is apparent that the *x*-ray examination of any stomach case must be conducted by one who is familiar not only with the physiology of the normal stomach, but also with normal *x*-ray findings. Two types of the normal stomach, as seen by the *x*-ray, are described. The normal stomach that Holzknecht describes has the pylorus at the lowest part of the stomach shadow. The normal stomach as described by Rieder exhibits a certain amount of lifting power (hübhöhe) of the lower or caudal pole to the pyloric orifice, consequently the caudal pole is the lowest part of the stomach shadow. The majority of bismuth-filled shadows that one sees upon the fluorescent screen present the Rieder form. The Holzknecht type is seen very infrequently. This may be due to the fact that most of the cases referred to the röntgenologist for stomach diagnosis necessarily possess a pathological stomach. If the röntgenologist makes it his practice to examine stomach cases in the recumbent position he will probably find more stomach outlines simulating the steer-horn shaped stomach. It is generally conceded, however, that the examination of all stomach cases should be made with the patient in the standing position with variations, as this is the posture in which the individual lives the greater part of his day, and it is also the posture in which one has the stomach hanging by its two supports at the cardiac and pyloric ends.

The technique for the fluoroscopic examination of the stomach embraces many details that should be understood by the clinician who is examining his case with the röntgenologist. The examination should be conducted in an absolutely dark room and the examining physicians should remain within this darkened room for at least ten minutes before the fluoroscope is used in order to accommodate the eye to the darkness. The fluoroscopic image at its best requires a good accommodation of the eye. Another point in technique is that the patient should be in a fasting condition before the bismuth is introduced, because the remains of a small meal would hinder a correct estimate of the fluoroscopic image.

It is apparent that this *x*-ray method of stomach examination offers much that cannot be obtained by other means. The work must be done by those familiar with it so that the results shall be of such value that the method cannot fall into disrepute through overzealous workers.

616 Commerce Building.

Treatment of Acute Pulmonary Edema.—Tranquilli advises the use in acute edema of venesection and other unusual means of treatment. Active pulmonary edema is of toxic origin, as is shown clearly in cases of nephritis, etc. Passive edema, on the contrary, is the result of mechanical factors. In most cases the origin is a mixture of the two, being toxi-mechanical. The necessity of interference is generally very urgent. The use of inhalations of oxygen, dry cups to the thorax, hypogastrium, and legs, with a sitting position, is advised. An abundant venesection is of great value, from the arm, hemorrhoidal vessels, and jugular vein at the same time. The legs up to the knees may be placed in hot water for two or three minutes, then in cold, and the heat repeated; this abstracts a large amount of blood from the general circulation. Another derivative, but less effective, is ligation of the extremities. Use of electricity to the pneumogastric is considered by the author to be dangerous. Injections of sulphuric ether, caffeine, strychnia, and sparteine are in order. Cardiotonic treatment is especially necessary in passive pulmonary edema. If there is intrapleuric effusion it is not advisable to evacuate it rapidly. A small amount of fluid may be removed with good results. Nitrite of amyl and nitroglycerine may do harm rather than good by vasodilation.—*Gazzetta Medica di Roma.*

MEDICAL RECORD.

New York, January 14, 1911.

ACUTE POLIOMYELITIS.

THAT the disease termed acute anterior poliomyelitis in the mortality statistics report of the Bureau of the Census for the registration cities and States of the United States for 1909 has gained a more or less firm foothold in this land seems evident. The Bureau reports 569 deaths from the disease during the year. Moreover, its prevalence appears to be increasing. In Canada, too, during the past few years acute poliomyelitis has shown itself with some frequency. At the present time in certain parts of Ontario there are several cases of the disease, the originating point and the center of the greatest prevalence being Hamilton. In two or three of the English midland counties an epidemic of cerebrospinal meningitis has been present, which from the accounts received presents so many features of close resemblance to acute poliomyelitis that it gives rise to the view that it must be a difficult matter to distinguish clearly between the two affections. In fact, Dr. Farrar, the British local government inspector, stated some time ago with regard to the epidemic in Leicestershire and Northamptonshire that while he had not collected sufficient data about three-quarters of the cases, they were of the type generally known as infantile paralysis.

In the United States and in Canada acute poliomyelitis is known as infantile paralysis and, in truth, there is in many ways much confusion between the two diseases and a correct diagnosis is not rapidly or easily made. According to Flexner it is not improbable that the mode of entrance and exit of the poison which causes acute poliomyelitis may be the same as the mode of entrance and exit of the poison which causes epidemic cerebrospinal meningitis and the two diseases may be disseminated in much the same way. It is true that they generally appear at different seasons of the year. Acute poliomyelitis reaches its height in midsummer and cerebrospinal meningitis in the late winter and early spring, but they sometimes overlap or succeed each other by very short intervals and hence the two diseases are extremely likely to be confused one with the other.

The onsets of the two diseases have most points in common, and although rigidity of the neck is a prominent symptom of cerebrospinal meningitis it is not wholly distinctive, as the neck is sometimes rigid in cases of acute poliomyelitis. Cerebrospinal meningitis has been termed spotted fever and in England is still commonly so termed, but it is not unlikely that skin eruptions occur almost as frequently in acute poliomyelitis as in epidemic cerebrospinal meningitis. Of course, as a matter of fact spots on the skin are not infrequently absent in cerebrospinal meningitis, and the occurrence of accidental eruptions in cases of so-called infantile paralysis is not impossible or even improbable.

As for differential symptoms it should be borne in mind that the sensorium remains, as a rule, clear in acute poliomyelitis and that a high temperature is not likely to last for longer than four or five days. Furthermore, optic neuritis is very seldom present, while it is common in cerebrospinal meningitis. Spinal puncture, however, is the only really definite method of early differentiation. The name acute anterior poliomyelitis is, with the exception of the word acute, a misnomer. In the majority of cases the seat of the disease is the spinal cord, but the brain is also attacked, although less frequently, and it is an error to suppose that the lesions are strictly those of an anterior poliomyelitis. Indeed, the malady is not a poliomyelitis at all; its effects are not confined to the gray matter of the spinal cord or the brain, but are present in the white matter also and both in the anterior and posterior horns.

Again, to denominate acute poliomyelitis infantile paralysis is almost as great a misnomer as to term epidemic cerebrospinal meningitis spotted fever, for the former disease attacks grown-up people and with almost invariably fatal results. In Ontario, for instance, quite a number of adults have been attacked by acute poliomyelitis and have died as the result.

The virus is very possibly not bacterial but of protozoan origin, and the disease may lend itself to treatment by immunizing methods. However, as yet the main source of protection must be looked for in preventive measures for the reason that the disease is positively recognizable only with the onset of the paralysis, but as it is infectious and possibly contagious strict isolation must be resorted to in order to check its spread.

TREATMENT OF PELLAGRA.

IN the *American Journal of Clinical Medicine* for December, 1910, are two articles on the treatment of pellagra. The first is by J. W. Torbett. In describing the symptoms of pellagra the author of this article mentions one symptom which is not generally noticed in the United States, namely, a feeling of numbness and paresthesia in the hands and feet. Patients suffering from these symptoms seem to be greatly benefited by treatment with the long static sparks. The general treatment used by Torbett is the administration of petroleum emulsion continuously for at least three weeks. Two patients who could not take it well benefited as greatly on teaspoonful doses of castor oil at bedtime. The petroleum was used with hypophosphite of lime and soda. As intestinal antiseptics and astringents a combination of zinc sulphocarbolate, 5i; bismuth subnitrate, 5ii; aqueous extract hydrastis and tinc-

ture of ginger, of each, ʒii, and elixir lactated pepsin, enough to make ʒii. One teaspoonful in water every two or three hours, sufficient to hold the bowels to three or four movements daily. If the discharges are checked more than this the nervous and mental symptoms always become worse. Torbett says that he has had very gratifying results from this form of treatment.

E. H. Bowling writes in the same journal that he has had very fair success in treating patients suffering from pellagra in the following manner: First the administration of one ounce of castor oil, then chlorine water every two hours, and a hypodermoclysis of one quart of physiological salt solution twice a day. The principle of this mode of treatment appears to be thorough cleansing and antisepsis of the bowels. The results of this method of treatment were encouraging. In both methods the treatment was such as would be demanded were the condition one of protozoan infestation of the intestines, a view that seems to be gaining ground among the students of the disease.

POLITICS VERSUS SCIENCE.

After eight years of service as attending physician to the City Hospital, New York, Dr. Theodore C. Janeway, at a meeting of the medical board on January 3, offered his resignation, which was accepted. In a statement issued to explain this action Dr. Janeway states that since the present Commissioner of Charities took charge there has been a change in the attitude toward the scientific work of the City Hospital and toward the medical board, and that the acts of the Commissioner have been such as to break down the authority of the medical board, which Dr. Janeway foretells will "eventually be nothing more than the Commissioner's rubber stamp"; and he calls upon the taxpayers to decide whether the City Hospital with its great responsibility to the sick poor shall be turned over to politicians and their satellites. The situation is rendered more acute by the fact that Dr. Janeway is also secretary and treasurer of the board of directors of the Russell Sage Pathological Institute, which was founded in 1907, when Mrs. Sage gave $300,000 for pathological and research work in connection with the hospitals and institutions on Blackwell's Island. The Institute receives from the city the use of a building rent free, and in addition between $5,000 and $6,000 a year, which is expended through the Commissioner's office for routine expenses. In exchange for this it gives to the city, laboratory and other service, which could not be otherwise obtained for less than two or three times this sum.

Recently a committee appointed by Commissioner Drummond presented a report recommending certain changes in the relations between the Institute and the City Hospital and the Department of Charities. This report was based on the results of an investigation of the Institute carried on by the committee unknown to the directors, because of alleged complaints concerning the work done for the City Hospital. Following this, Commissioner Drummond issued an order placing the work of the Russell Sage Institute, in so far as it acts as a city laboratory, under the supervision of the medical board of the City Hospital, and appointing a committee of the medical board to confer with the trustees of the Institute as to the conditions under which future pathological work shall be conducted. The appointment of this committee without consultation with the board which it is supposed to represent, is one of the specific acts objected to by Dr. Janeway. Commissioner Drummond, furthermore, dismissed an advisory committee consisting of Drs. Edward G. Janeway, Simon Flexner, Joseph Blake, W. Gilman Thompson, Horst Oertel, Daniel M. Stimson, Clinton M. Bagg, Prince A. Morrow, and Joshua Van Cott, and substituted therefor a body of his own choosing, consisting partly of laymen. In reply to protests against such treatment of the medical staff of the Sage Institute, Mr. Drummond replies that the work now done by the Institute could be done quite as adequately in a city-controlled laboratory, and says or implies that the Sage Institute can get out if it does not want to be under political control.

Evidently the income from the Sage fund of $300,000 is expended too exclusively for the benefit of science. The "practical" politicians, who are trying to regain their hold on the departments of the city government, seem to have made a beginning. If Commissioner Drummond is too weak to oppose them, the facts in the case should be brought to the attention of Mayor Gaynor, for unless the Commissioner can advance better reasons for his reach after the control of the Sage Institute than he has yet given, he will have amply demonstrated his unfitness for the responsible position he occupies.

American Life Waste.

A pamphlet entitled "American Life Waste, Where and How It Is Increasing," has been published recently by E. E. Rittenhouse, president of the Provident Savings Life Assurance Society. The pamphlet is graphically written, well compiled, and, although manifestly composed for popular consumption, is founded upon undoubted facts. It would be a waste of time to insist that lives are frequently carelessly thrown away; this must under existing conditions happen in all industrial countries, but the point perhaps that requires to be driven home is that in this country less care is taken to conserve life than in many other countries. Facts that may be especially noticed are that since 1880 the general death rate has decreased up to age 40, while above 40 it has steadily increased. From age 40 to 50 it has increased 13 per cent.; from 50 to 60, 29 per cent.; 60 and over, 26 per cent. This increase, then, is almost wholly due to degenerative diseases. The increase of cancer has been so often referred to that it needs little comment. The mortality from diseases of the heart, arteries, and kidneys appears to be increasing by leaps and bounds. In the pamphlet under discussion it is stated that to check the enormous loss of life, a large proportion of which is preventable by the use of ordinary measures, the national government can spare but 1.3 per cent. of its total expenditure; Greater New York but 1.7 per cent., and 148 American cities but 1.8 per cent. The State of New York spends for the protection

of game, fish, and forests about four times more than it spends for the State Health Department. Of course, it is clearly apparent that more money by far should be expended by States and municipalities on the prevention of pollution of lakes, rivers, and streams, on providing a good milk supply, on strict supervision of all kinds of foods, and especially on the erection of sanitary buildings for the working classes. If these matters received the undivided attention of federal, State, and municipal authorities the waste of life in this country would be greatly lessened.

Patent Medicines in Great Britain.

The British Privy Council has just issued a report on the "Practice of Medicine and Surgery by Unqualified Persons." In this report patent and proprietary medicines are also discussed. The suggestions put forward are that the composition of all advertised remedies should be stated, that their prescription and analysis should be determined by the government analyst, that the public sale of headache powders and the like should be prohibited and that the sale of infant foods should be regulated. So far as restriction or regulation of the sale of nostrums is concerned Great Britain is far behind any country of the civilized world. As a matter of fact, there are scarcely any restrictions on the trade in such medicines. How great is the sale which patent medicines enjoy in Great Britain may be judged from the fact that the stamp duty on them brought into the Government the sum of $1,670,705 for the year ended March 31, 1908. In that year 41,757,575 proprietary articles were stamped, and it is estimated that the public paid for them about $12,114,000. It has been more than once mooted that a select committee of the British House of Commons would be appointed to consider the sale of patent medicines, but as yet nothing has been done. The patent medicine interests are rich and powerful and up to the present have been able to shelve any projected legislative considerations.

News of the Week.

Harvey Society.—The fourth lecture of the Harvey Society will be given by Prof. Arthur R. Cushny of the University of London, England, on Saturday evening, January 14, at 8.30 o'clock, at the New York Academy of Medicine, 17 West Forty-third street. The subject of the lecture will be "The Therapeutics of Digitalis."

City Death Rate.—During the week ending December 31 there was a total of 1,666 deaths in New York City, exceeding the total for the last week of 1909 by 104. The death rate for the week was 18.10 in 1910 as compared with 17.29 for 1909. There was a reduction in child mortality, but an increased mortality among adults suffering from respiratory diseases. Thus, pneumonia caused 358 deaths during the week, 71 more than a year ago; pulmonary tuberculosis caused 180, an increase of 40, and influenza caused 27, an increase of 14. Heart disease was the cause given in 238 cases and typhoid fever in 10.

Aged Colored Woman.—Mrs. Hettie Jankins, a colored woman of Lancaster, Pa., who died recently, was born in 1793, and was therefore almost 118 years old. She was the mother of twenty-five children, only one of whom outlived her.

Mme. Curie Barred.—Pleading respect for tradition, the Institute de France, at a meeting on January 4, declared by a vote of 90 to 52 against the admission of women. The issue was raised by the proposal to elect Mme. Curie to the Academie des Sciences, as a successor to her husband. While asserting the force of custom, the Institute, however, disclaimed any desire to dictate to the five academies of which it is composed, and it is possible that when Mme. Curie's name is acted upon directly the action of the Institute may be reversed.

"The Journal of Experimental Medicine."—Beginning with January, 1911, the *Journal of Experimental Medicine* will be issued monthly instead of bi-monthly as heretofore. This will mean the publication of two volumes a year, each containing about 600 pages.

College of Physicians of Philadelphia.—At a stated meeting of this society, held January 4, the following officers were elected for the ensuing year: *President,* Dr. George E. de Schweinitz; *Vice-President,* Dr. James C. Wilson; *Secretary,* Dr. Thomas R. Neilson; *Treasurer,* Dr. Richard H. Harte; *Honorary Librarian,* Dr. Frederick P. Henry; *Censors,* Drs. Richard C. Cleeman, S. Weir Mitchell, Arthur V. Meigs, James Tyson; *Councillors,* Drs. Francis X. Dercum and William T. Shoemaker.

Bellevue Alumni Prizes.—The two annual prizes of $100 each, offered by the Society of Alumni of Bellevue Hospital to the members of the house staff for "the best paper based on observation and clinical studies," have been awarded this year to Dr. Alexander Hunter Schmitt for an essay entitled, "The Relation of the Cervical Smear to the Diagnosis and Treatment of Diseases of the Fallopian Tubes," and to Dr. Frederick Lane Brown for an essay entitled "Report of a Case of Infective Endocarditis Associated with an Unidentified Liquefying Bacillus."

Ambulance Surgeon Hurt.—Dr. Edward Eugene Walker, interne at the Fordham Hospital, New York, was seriously injured, on January 3, when the ambulance in which he was conveying a patient to the hospital was struck by a trolley car at the corner of 189th and Hoffman streets. The other occupants of the ambulance were bruised but not severely hurt. Dr. Walker is a graduate of McGill University, Montreal, in the class of 1909, and has been at Fordham Hospital for the last six months.

Colonel Joseph B. Girard, the oldest surgeon in point of service in the United States Army, was retired from active service on December 26. Dr. Girard received his appointment on May 14, 1867, and saw many years of service in Indian warfare.

Typhoid Vaccination.—Major-General Wood, Chief of Staff of the United States Army, has issued a general order directing all commanding officers throughout the service to use their best efforts to induce all officers and men in their commands, and all civilians connected with the army, to submit to vaccination against typhoid fever. The order is not compulsory except under such conditions as may justify it.

Bequest Invalid.—Because of failure to attach his signature, the will drawn up by Dr. W. G. MacDonald, who died recently in Albany, bequeathing his library and instruments and $50,000 to the Albany Hospital, is void, and the estate will revert to the lawful heirs.

Opium Congress.—May 30, 1911, is the date finally agreed upon for the opening of the Inter-

national Congress for the Suppression of the Opium Traffic at The Hague. It is stated that the United States will support England in the proposal to include morphine and cocaine.

Venezuelan Sanitary Fund.—The Government of Venezuela has issued a decree setting aside one per cent. of the import duties collected for the creation of a fund to be used for sanitary purposes.

Antivivisection Agitation.—Basing its action upon information that "acts of cruelty under the name of 'animal experimentation' are being performed in this city and other places in this State, nominally for the benefit of science and the human race, the acts involving such mutilation and suffering on the part of the animals treated as to demand that the alleged good obtained thereby should be clearly and undeniably demonstrated," the Society for the Prevention of Cruelty to Animals of New York recently passed some resolutions. The Committee on Legislation was also directed to call upon Governor Dix to ask him to include in his message to the Legislature some suggestions for the supervision of vivisection.

The Phipps Institute of the University of Pennsylvania has arranged a special course in tuberculosis for graduates in medicine as a part of the regular postgraduate course at the University. Drs. D. L. Edsall and Alien J. Smith, and Mr. Alexander Wilson, Director of the Institute, have been appointed a committee to arrange for the details of the course. Dr. Edsall has been appointed Consulting Physician and Dr. Edward Martin Consulting Surgeon to the Institute.

Dr. Ernest J. Lederle, Commissioner of Health of the City of New York spoke at a meeting of the City Club, on January 7, and outlined his plans for the reorganization of the department along lines which will promote its efficiency.

Straus Milk Depots.—In response to many appeals Mr. Straus has decided to continue his support of depots for the distribution of milk for infants as previously, and has stated that he will continue to do so until relieved of responsibility. New York City has recently appropriated the sum of $40,000 for the purpose of opening fifteen additional depots, five in Manhattan, eight in Brooklyn, one in the Bronx, and one in Queens.

Edward N. Gibbs Memorial Prize.—The New York Academy of Medicine announces the following conditions of granting this prize: (I) The Council of the New York Academy of Medicine is to appoint a permanent Committee of Award consisting of five of its members to be known as the Edward N. Gibbs Prize Fund Committee. (II) The said committee is to have the selection of the candidates and the awarding of the prize. (III) The method of award is as follows: (1) The committee shall advertise the prospective award at intervals of not less than two years in appropriate medical journals and otherwise. (2) Candidates must be physicians of not less than three years' experience, since graduation, in clinical and laboratory work; must be residents of the United States; and shall furnish the committee with evidence of research already performed and of ability to prosecute the special researches for which the prize is founded. (3) Such researches may be conducted in any hospital or medical laboratory approved by the committee, wherever it may be situated. (4) The researches shall comprise original work only in any or all of the following subjects: the causation, pathology, and new methods of treatment of diseases of the kidney. (5) From the applicants the committee shall select the one offering the best credentials as to ability to conduct original investigation, and to him shall be awarded from time to time during the research the income of the prize fund for such time as may have been occupied by the research, providing, however, that the total time shall not exceed three years, and provided that the committee shall at all times retain the power to reject unsatisfactory work from the award. It is understood, moreover, that the expense of advertising and of publication of the researches be met from the income of the prize fund, and that when no research is forthcoming the income for the current year be not awarded, but added to the principal of the prize fund. (6) The completed research shall be presented in the form of a thesis and published under the auspices of the New York Academy of Medicine, bearing title substantially as follows: "The Edward N. Gibbs Memorial Prize for Original Research in Diseases of the Kidney Awarded Through the New York Academy of Medicine. A Thesis upon the by ———. M.D. Published under the direction of the New York Academy of Medicine." (A brief note should be published with the thesis, setting forth the object of the Memorial Prize.) It should be understood for all time that it is the fundamental purpose of the donors to promote the study of the diseases of the kidney with the object of relieving human suffering, but as it is impossible to forecast the direction of special scientific research it should be left within the discretion of the permanent committee of the Academy to modify the details of method of award of the prize in regard to mode of selection of the candidates, should occasion demand in future years. Signed: William M. Polk, M.D., President; John H. Huddleston, M.D., Recording Secretary.

Texas Vital Statistics.—For the months of November, the Texas State Department of Health reports 4,336 births and only 1,908 deaths. During the month two sets of triplets were born, and fifty-seven sets of twins, fifty-one being white and six colored.

Plague in China.—Many cases of bubonic plague have been reported in the province of Harbin, China, twenty-three deaths occurring on Christmas day alone.

Mobile County (Alabama) Medical Society.—At the annual meeting held in Mobile on December 10 the following officers were elected: *President*, Dr. Marion J. Bancroft, Mobile; *Vice-President*, Dr. Tucker H. Frazer, Mobile; *Secretary*, Dr. M. Toulmin Gaines, Mobile.

El Paso County (Colorado) Medical Society.—At the annual meeting in Colorado Springs on December 14 the following officers were elected: *President*, Dr. Z. H. McClanahan; *Vice-President*, Dr. O. R. Gillett; *Secretary*, Dr. L. H. McKinnie; *Treasurer*, Dr. George B. Gilmore.

Defiance County (Ohio) Medical Society.—The election of officers held on December 14 resulted as follows: *President*, Dr. M. B. Stevens; *Vice-President*, Dr. Blue; *Secretary-Treasurer*, Dr. J. B. Ury.

Fourth District (South Dakota) Medical Society.—The annual meeting of the society was held

at Pierre on December 16, officers for the ensuing year being elected as follows: *President*, Dr. C. M. Hollister; *Vice-President*, Dr. N. B. Gearhart; *Secretary-Treasurer*, Dr. J. M. Walsh.

Travis County (Texas) Medical Society.—The following officers were elected at the annual meeting on December 20: *President*, Dr. S. E. Hudson; *Vice-President*, Dr. Z. T. Scott; *Secretary*, Dr. George M. Decherd.

Bexar County (Texas) Medical Society.—At the annual meeting held on December 14 the following officers were elected: *President*, Dr. Malone Duggan; *Vice-President*, Dr. T. L. Moody; *Secretary*, Dr. Thomas D. Dorbandt; *Treasurer*, Dr. E. V. DePew.

Harris County (Texas) Medical Society.—At the annual meeting on December 16 the following officers were elected: *President*, Dr. E. F. Cooke; *Vice-President*, Dr. Vard H. Hulen; *Secretary*, Dr. L. Allen.

Williamson County (Texas) Medical Society.—At the annual meeting on December 17 the following officers were elected: *President*, Dr. D. M. Cooke, Granger; *Vice-Presidents*, Dr. G. L. Robertson, Leander; Dr. G. E. Hueschen, Georgetown; *Secretary*, Dr. C. C. Block, Georgetown.

Marinette-Menominee (Wisconsin) Medical Society.—At the annual meeting on December 14 the following officers were elected: *President*, Dr. C. R. Elwood, Menominee; *Vice-President*, Dr. D. R. Landsborough, Daggett; *Secretary-Treasurer*, Dr. E. V. McComb, Menominee.

Nacogdoches County (Texas) Medical Society.—The annual meeting was held on December 14, officers for the ensuing year being elected as follows: *President*, Dr. J. H. Barham; *Vice-President*, Dr. T. Hardeman; *Secretary-Treasurer*, Dr. R. P. Lockey.

Madison County (Alabama) Medical Society.—At the annual meeting held in Huntsville on December 13 the following officers were elected: *President*, Dr. W. W. Haden; *Vice-President*, Dr. I. W. Howard; *Secretary* and *Treasurer*, Dr. Edgar Rand.

Shelby County (Alabama) Medical Society.—At a meeting of the society held on December 13, at Calera, the following officers were elected for the ensuing year: *President*, Dr. A. T. Rowe, Columbiana; *Vice-President*, Dr. E. S. Miller, Columbiana; *Secretary*, Dr. J. F. Trucks, Helena; *Censor*, Dr. O. E. Black, Wilsonville.

Philips County (Arkansas) Medical Society.—The following officers were elected at a meeting held in Helena on December 12: *President*, Dr. L. Hall, Turner; *Vice-President*, Dr. A. A. Horner; *Secretary* and *Treasurer*, Dr. M. Fink, Helena.

Sonoma County (California) Medical Society.—The following officers were elected at a meeting held in Santa Rosa on December 11: *President*, Dr. J. Walter Sewall, Healdsburg; *Vice-President*, Dr. R. M. Bonar, Santa Rosa; *Secretary*, Dr. Jackson Temple, Santa Rosa; *Treasurer*, Dr. F. O. Pryor, Santa Rosa; *Censor*, Dr. J. W. Scammell, Windsor.

Fulton County (Georgia) Medical Society.—At the annual meeting on December 15, the following officers were elected: *President*, Dr. E. C. Ballenger; *Vice-President*, Dr. L. C. Clarke; *Secretary*, Dr. R. R. Daley; *Treasurer*, Dr. A. H. Lindoine.

Effingham County (Illinois) Medical Society.—The following officers were elected at a meeting held on December 13: *President*, Dr. J. H. Walker; *Vice-Presidents*, Dr. F. W. Goodell and Dr. E. W. Brooks; *Secretary*, Dr. H. Taphorn; *Treasurer*, Dr. G. H. Haumesser.

Vermilion County (Illinois) Medical Society.—At a meeting held in Danville on December 12, the following officers were elected: *President*, Dr. E. E. Clark; *Vice-President*, Dr. J. T. Fisher; *Secretary* and *Treasurer*, Dr. Solomon Jones; *Censor*, Dr. Leo Fairhall.

Mills County (Iowa) Medical Society.—The annual meeting was held at Emerson on December 8, officers for the ensuing year being elected as follows: *President*, Dr. Merritt; *Vice-President*, Dr. Christy; *Secretary-Treasurer*, Dr. Donelan.

Buchanan County (Iowa) Medical Society.—At the annual meeting in Winthrop on December 9, the following officers were elected: *President*, Dr. H. H. Hunt, Hazleton; *Vice-President*, Dr. J. H. McGready, Independence; *Secretary-Treasurer*, Dr. B. B. Sells, Independence.

Fayette County (Kentucky) Medical Society.—At the annual meeting on December 13, officers were elected as follows: *President*, Dr. B. F. Van Meter; *Vice-President*, Dr. W. N. Offutt; *Secretary*, Dr. L. C. Redmond; *Treasurer*, Dr. B. L. Coleman.

Durham County (North Carolina) Medical Society.—Officers were elected at the annual meeting on December 9, as follows: *President*, Dr. W. A. Graham; *Vice-President*, Dr. A. Cheatham; *Secretary-Treasurer*, Dr. L. S. Booker.

Garfield County (Oklahoma) Medical Society.—The following officers were elected at the meeting held on December 12, at Enid: *President*, Dr. Kelso; *Vice-President*, Dr. Shanty; *Secretary*, Dr. Jones.

Columbia County (South Carolina) Medical Society.—At the annual meeting held in Columbia on December 12, the following officers were elected: *President*, Dr. S. B. Fishburne; *Vice-President*, Dr. H. W. Rice; *Secretary-Treasurer*, Dr. Mary M. Baker.

McLennan County (Texas) Medical Society.—At the annual meeting of December 8, the following officers were elected for the coming year: *President*, Dr. M. L. Lankford, Mart; *Vice-President*, Dr. B. L. Scott, Waco; *Secretary-Treasurer*, Dr. Merchant W. Colgin.

Bell County (Texas) Medical Society.—The following officers were elected at the annual meeting held in Temple on December 8: *President*, Dr. A. B. Craine, Belton; *Vice-President*, Dr. F. A. Watt, Pendleton; *Secretary-Treasurer*, Dr. E. J. Burns, Temple.

Salt Lake County (Utah) Medical Society.—At the annual election on December 12, the following officers were elected: *President*, Dr. E. W. Whitney; *Vice-President*, Dr. T. C. Gibson; *Secretary*, Dr. W. Brown Ewing; *Treasurer*, Dr. R. R. Hampton.

Seventh District (Texas) Medical Society.—The following officers were elected at the annual meeting on December 23, held in Austin: *President*, Dr. T. J. Bennett, Austin; *Secretary-Treasurer*, Dr. L. B. Bibb, Austin.

American Society of Tropical Medicine.—The eighth annual meeting of this society will be held

in New Orleans, on Thursday and Friday, May 18 and 19, 1911. The secretary, Dr. John M. Swan, The Glen Springs, Watkins, N. Y., will be glad to receive the titles of papers to be offered at the meetings.

The Late Dr. Alexander.—At a meeting of the Medical Board of Bellevue Hospital, held January 1, 1911, the following minute was adopted:

We Record with profound sorrow the startling removal from our circle, by death, of Dr. Samuel Alexander. Dr. Alexander had been continuously connected with Bellevue Hospital from the day of his graduation in medicine until the day of his death. Dr. Alexander's cheerful personality, his kind-hearted counsel, and his ever gracious championship of the best of things in our affairs was an inspiration and a guide, to which we gladly yielded our differences and gave hearty approval. From our profession is taken a pioneer in surgery, and an able exponent of substantial advance; from our hospital gatherings an enduring and tender personality, whose virtues we each can well afford to emulate, and from the poor and the unfortunate to whose afflictions Dr. Alexander administered abundantly and successfully an earnest, sympathetic, and noble nature is taken away.

Obituary Notes.—Dr. Braxton Wise of Benton, La., a graduate of the Tulane University of Louisiana Department of Medicine, in 1883, and a member of the Louisiana State and Bossier County Medical Societies, died suddenly on December 27, aged 55 years.

Dr. John W. Blanton of Meadowlawn, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1884, died at his home on December 26, aged 58 years.

Dr. Willis H. Vittum of St. Paul, Minn., a graduate of the Tulane University of Louisiana Department of Medicine, in 1875, and a member of the American Medical Association and the Minnesota State and Ramsey County Medical Societies, died suddenly of apoplexy on December 29.

Dr. H. H. Haden of Hollypond, Ala., a graduate of the Medical Department of Vanderbilt University, Nashville, Tenn., in 1886, died of heart disease on December 25.

Dr. Damon S. Cummings of Waseca, Minn., a graduate of the Northwestern University Medical School in 1876, and a member of the American Medical Society and the Minnesota State and Waseca County Medical Societies, died at his home on December 25, aged 60 years.

Dr. John W. Pitts of Berlin, Md., a graduate of the University of Pennsylvania Department of Medicine in 1867, and first mayor of Berlin, died at his home on December 27, aged 69 years.

Dr. Leon A. Lapalme of Montreal, Canada, a graduate of the Medical Department of Victoria College, Ontario, in 1878, died at his home on December 28, aged 58 years.

Dr. Ray W. Chamberlain, an assistant resident physician of the City Hospital of St. Louis, Mo., a graduate of the Medical Department of Washington University in 1909, and a member of the Missouri State and St. Louis Medical Societies, died on December 23 of typhoid fever.

Dr. James L. Clayton of Clayton, La., a graduate of the Medical Department of the University of Arkansas, Little Rock, in 1891, died at his home on December 23, aged 52 years.

Dr. William H. Krause of New York a graduate of the New York Homeopathic Medical College in 1873, a member of the American Institute of Homeopathy and of the New York State Homeopathic Society, and consulting physician to the Hahnemann Hospital, died at his home of kidney disease on January 7, aged 68 years.

Dr. John Perrine Gilbert of Lyons, N. Y., a graduate of the New York University Medical Department in 1856, died at his home on January 7, aged 81 years. He resigned charge of the Albany Eye and Ear Infirmary in 1861 to become a naval surgeon during the Civil War. He then entered the army service at Riker's Island, and Elmira, Chemung County, N. Y. Until 1870 he lived in Long Island City, Borough of Queens County, where he was postmaster.

Dr. Austin W. Foreman of Vinita, Oklahoma, a graduate of the Louisville Medical College in 1877, died at St. John's Hospital, Springfield, Missouri, after a long illness, on December 18, aged 55 years.

Dr. Edward A. Flewellen, a retired physician of The Rock, Georgia, a graduate of Jefferson Medical College, Philadelphia, in 1851, inspector of hospitals for the Confederate Government during the Civil War, died at his home on December 9, aged 91 years.

Dr. John Burgess Gaither of China Grove, North Carolina, a graduate of the College of Physicians and Surgeons, Baltimore, in 1869, a member of the North Carolina State and Rowan County Medical Societies, died at his home on December 17, aged 65 years.

Dr. Samuel P. Smith of Cornelia, Georgia, a graduate of the Atlanta College of Physicians and Surgeons in 1901, died on December 12.

Dr. James M. Wheat of Redlands, California, a graduate of the Albany Medical College, New York, in 1853, died at his home on November 27.

Dr. Presley C. Hunt of Washington, a graduate of the University of Georgetown Medical Department in 1892 and a member of the Medical Society of the District of Columbia, died at the John Hopkins Hospital after a brief illness on December 15, aged 39 years.

Dr. William B. Hardy of Belleville, Kansas, a graduate of the Jefferson Medical College, Philadelphia, in 1856, died at his home after a short illness on December 6, aged 80 years.

Dr. Giles F. Roosevelt of Denver, Colorado, a graduate of the Denver Homeopathic Medical College in 1902, and a member of the Colorado State and Denver County Medical Societies, died at his home of pulmonary tuberculosis, on December 10, aged 36 years.

Dr. William C. Dake of Nashville, Tennessee, a graduate of the University of Nashville, Medical Department, in 1872, and of the New York Homeopathic Medical College in 1873, ex-president of the Homeopathic Medical Society of Tennessee, and of the Southern Homeopathic Medical Association and a member of the Hahnemann Medical Club of Nashville, died at his home suddenly on December 9, aged 58 years.

Dr. George E. Goodfellow of San Francisco, California, a graduate of the University of Wooster Medical Department, Cleveland, Ohio, in 1876, a member of the American Medical Association and of the California State and San Francisco County Medical Societies, died in the Angelus Hospital at Los Angeles, on December 9, aged 54 years.

Dr. Augustine Gandier of Sherbrooke, Quebec, a graduate of the Faculty of Medicine of Queens

University and the Royal College of Physicians and Surgeons, Kingston, died at his home after a long illness on December 16, aged 44 years.

Dr. George L. Ezzard of Atlanta, Ga., a graduate of the Southern Medical College of Atlanta in 1891, a member of the Georgia State and Cobb County Medical Societies, died on December 12, aged 44 years.

Dr. Dexter A. Smith of Chicago, Ill., a graduate of the University of Georgetown in 1884, died at his home on December 17, aged 60 years.

Dr. Clarke Gapen of Madison, Wis., a graduate of the Northwestern University Medical School, Chicago, in 1875, a member of the American Medical Association and the Wisconsin State and Dane County Medical Societies, died at his home suddenly on December 17, aged 60 years.

Dr. Stefano Joseph Hickey of Philadelphia, Pa., a graduate of the Jefferson Medical College in 1888, and a member of the Pennsylvania State and Pennsylvania County Medical Societies, and of the Medico-Legal Society, died at his home on December 12, aged 45 years.

Dr. George W. Smith of Philadelphia, Pa., a graduate of the Hahnemann Medical College and Hospital of Philadelphia in 1876, died at his home on December 15, aged 68 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

POLITICS IN THE PROFESSION—EHRLICH'S 606 VEL SALVARSAN — ACROMEGALY — HOSPITAL SUNDAY FUND—AN ANTIVIVISECTION MEETING.

London, December 23, 1910.

You will have learned before this date that we have gone through the excitement of a general election, and that "now the hurlyburly's done" it looks as if all the turmoil might have been saved. All parties are "as they were," so few are the changes. The result is said to be unprecedented. Even the strength, or rather the weakness, of the profession in Parliament remains as it was. It is true we have talked politics for a few minutes whenever we have met while the election was going on, but as a body we have been too apathetic to influence results, and in this we have for once acted in much the same way as the man of the public.

Ehrlich's 606 has now had a trial by a number of specialists, some of whom speak favorably of it, but others are very doubtful of what will be the final outcome. Ehrlich himself considers the first stage of its trial past and the results so favorable that only the question of permanency remains for further investigation. That a definite effect on the tissues is made seems to be established, and that it is safer than atoxyl and yet more efficacious is believed by many observers. Others, however, say that the results have been grossly exaggerated, both as to its specific influence and the number of cures—to use the favorite word of its advocates. As to danger, it is said to have proved fatal in some twelve cases, most of them occurring at first before adequate precautions were carried out, and were so distributed over some 12,000 cases in which it has been administered. The existence of danger is certainly undeniable in the face of the precaution insisted on by Professor Ehrlich, who in putting it on the market, protects it under the name "salvarsan" so as to secure that none is issued which has not been biologically tested and proved to be comparatively safe. Moreover, it is said that it will be comparatively painless—an important point, for many have found the injections very painful. Indeed, some of our surgeons have preferred venous transfusion for this reason. Mr. J. B. Byles, who has urged this mode of administering mercury for some three years, naturally would favor the plan for the newer drug if it could be shown to be free from risk. If the spirochetes are to be destroyed by a single dose, as many suppose, certainly the surest way would be by its direct introduction into the blood. Let me collate some other statements.

At the London Hospital the treatment has been carried out in sixteen cases where Dr. J. McIntosh, the research scholar, reported two or three months ago that he had experimented on the spirochetes of relapsing fever without injury to the animals subjected to the drug. He and Dr. Fildes have been observing the sixteen cases mentioned, most of them being under the care of Dr. Sequeira. They agree that the *Spirochæta pallida* is rapidly destroyed by 606, none being found twenty-four hours after the injection, even when the number has been large. In five to twelve hours most of them had been destroyed. They did not find such marked leucocytosis as many observers have reported, but the effect on the lesions was early and distinct. The temperature rose one or two degrees within twelve hours and then rapidly fell with profuse sweating.

Mr. Ernest Lane remarked at the Harveian Society that enthusiasts had minimized the pain produced and that Ehrlich had admitted a rather long list of contraindications. Two cases of blindness had been recorded and other two hinted at. He had submitted some cases to injections by Sir A. Wright and Mr. McDonagh, the results being in the main about as favorable as mercury would produce. One case relapsed twice and had to be treated by injections of grey oil, though it had been prematurely reported in the *Lancet* as a success for 606. Altogether, out of seventeen cases five called for no enthusiasm, but 606 was a useful drug in the rare cases in which mercury could not be tolerated. Laboratory research, valuable as it was, could not replace clinical experience.

Sir A. Wright, speaking from the laboratory standpoint, said 606 caused the spirochetes to disappear and the risk was infinitestimal. Probably the clinical manifestations afterward were due to secondary streptococcal or staphylococcal infection.

Mr. Shillitoe related some successful cases, and then Mr. Campbell Williams mentioned three fatal cases in addition to the twelve previously reported, and suggested that some "cures" were in nervous para-syphilitics.

At the Medical Society of London Dr. D. Ferrier had a paper on acromegaly. The view that it is one of diminution or absence of the secretion of the pituitary gland is widely held, is supported by the case in which destructive lesions have been found post mortem, and is comparable to the condition of the thyroid in myxedema. Others have held that the disease is due to the contrary cause—excessive secretion, especially of the anterior lobe. Dr. Ferrier seemed rather inclined to the latter view, and he is supported by the fact that acromegaly is aggravated by the administration of pituitary extracts. On the other hand, it is not to be forgotten that the tumors of the gland have been found when there was neither acromegaly nor giantism. But in such cases the symptoms of cerebral tumor were generally

more pronounced and were considered localized posterior to optic chiasma. Headache, sickness, and some mental alteration had been observed, mostly accompanied by somnolence. Bitemporal hemianopsy had been said to be pathognomonic. Blindness in one eye had been noted, as had various forms of oculomotor paralysis, but optic neuritis was rare. There might be primary optic atrophy and Fröhlich's syndrome was common. Such cases were often associated with polyuria and glycosuria and were rapidly fatal. Neoplasms of various kinds were found in the hypophysis or invading it. Several cases of successful removal have been reported—followed by improvement in the general condition. Still, many pathologists think the local lesion does not account for the general state, and look rather to deranged equilibrium of the internal secretory organs, all of which are in association and constitute a "multiglandular syndrome." This view is supported by the fact that the pituitary has been seen to hypertrophy after thyroidectomy, and the thyroid in the same way to hypertrophy after the removal of the pituitary.

The meeting of the Hospital Sunday Fund followed a day or two after that of King Edward's Fund which I reported last week. There was again an expression of discontent about the relation of St. George's Hospital to the school, and one clergyman went so far as to move that the grant be kept back until the King's Fund had publicly declared its satisfaction. The Lord Mayor, presiding, said this fund was under no obligation to conduct its affairs under the direction of another, and stated that the hospital had a discretionary fund from which alone would be taken any support they gave to the school. Sir William Church said the award was made on exactly the same terms as to all other hospitals. The smaller grant the previous year was because legacies had come in that year. In all cases a basis in accordance with the cost of the patients was formed, and then each hospital got its share according to the figures. The clergyman remaining dissatisfied, a vote was taken and his view repudiated. The report was adopted and the Council re-elected, and June 18 fixed as Hospital Sunday for 1911.

At an antivivisection meeting held at Ware (Herts), the usual misstatements were made, including the extremely ridiculous one that enormous profits were made by the preparation of serums. The *Hertfordshire Mercury* reported the meeting and has since inserted a refutation of the several flagrant falsehoods, signed by all the resident doctors. It would have been better if some of them had attended the meeting and replied at the time.

These antis every now and then catch a qualified practitioner to support them against the practically unanimous opinion of the profession as well as of men whose views are of any value. At this meeting they trotted out a Dr. Forbes Winslow, whose speech was not calculated to do credit to the name he inherits. He said that in his forty years' hospital experience "he had never seen a single case of disease treated by anything that had been learned from vivsection." He did not say he had never heard of Harvey's discoveries, so I hardly like to think he was only boasting of his ignorance. Yet the other explanation would be a deliberate attempt to deceive a popular audience. As to his vaunted *hospital* experience, it consists, so far as I know, of the superintendency and proprietorship of lunatic asylums. The chairman of the meeting at Ware indulges in hunting. "No," says his wife, who is a one-idea anti. He himself says "he does not look at the death of the fox if he happens to be near." His neighbors say, "Why go out riding in a red coat, whenever the hounds are out, if you are not hunting?"

Dr. James Edward Pollock died on the 18th inst., in his ninety-third year. For more than a generation he held a foremost place among our authorities on chest cases. He served the full time on the Brompton Hospital and his lectures delivered there were published in 1856 (*Lancet*), and a later course in 1874 (*Medical Times and Gazette*). Other important contributions to the societies and journals came from his pen, but the most known was perhaps his volume on "Prognosis in Consumption," first issued in 1865. He was physician extraordinary to Queen Victoria. At the College of Physicians he became Fellow in 1864, Senior Censor and pro-President in 1893, gave the Croonian lectures in 1882 and the Harveian oration in 1889.

The death is announced of Surgeon-General John Meane at the age of eighty-two. He took the M. R. C. S. in 1850 and joined the Army Medical Department two years later. He saw service in the Crimea and was wounded at the siege of Sebastopol. He took part in the attacks on the Redan; was mentioned in despatches and received the medal with clasp, also the Turkish medal. He took part in the Afghan War, 1878-1880, and was again mentioned in despatches and awarded the medal. He retired in 1881.

OUR CANADIAN LETTER.

(From our Special Correspondent.)

CONTROL OF BOVINE TUBERCULOSIS IN CANADA AND IN THE UNITED STATES—THE WATER SUPPLY OF TORONTO—BILL FOR RECIPROCITY IN MEDICAL PRACTICE IN CANADA—MILK IN TORONTO—DESTRUCTION BY FIRE OF THE TORONTO FREE HOSPITAL FOR CONSUMPTIVES, AT WESTON—SCHOOL MEDICAL INSPECTION IN TORONTO—WEST TORONTO ABATTOIR—NEW SHIP FOR DR. GRENFELL—TYPHOID FEVER IN THE QUEEN'S OWN REGIMENT—GENERAL HOSPITAL SURGICAL WING—COCAINE HABIT IN MONTREAL—SMALLPOX IN QUEBEC—A NEW TEN-STORY HOSPITAL FOR TORONTO—ACCIDENT TO DR. CHAS. A. HODGETTS—ASYLUM BURNED TO THE GROUND AT BRANDON, MANITOBA.

Toronto, January 3, 1911.

Chiefly under the auspices of the committee on public health of the Canadian Commission on Conservation, a commission was appointed, composed of members of the medical and veterinary professions, with a sprinkling of practical laymen, to inquire into bovine tuberculosis and to report thereon. The report has been published recently, and contains a mass of valuable information. Most of the conclusions have been arrived at previously, but the report is an excellent summary of present-day knowledge of bovine tuberculosis and the means of eradication and prevention. It may be said that the commission takes the view that bovine tuberculosis is a distinct menace to the human race, and therefore its recommendations for the eradication and prevention of the disease among domestic animals are far reaching. With regard to legislation, it is recommended by the commission that legislation be enacted regarding the control and eradication of tuberculosis among domestic animals; that the laws of the United States and other American countries for the admission into America of animals from without be made stringent and as much alike as possible.

and that the laws governing the interstate and interprovincial movement of cattle and that between different American countries be harmonized. The laws governing interstate and interprovincial movement of cattle should be of such a character that every State and every province will be free in its eradication work from unnecessary difficulties due to the existence of the disease in other states and provinces.

The water supply of Toronto continues to vex and harass the minds of the members of the City Council, the Health Department, and of the ordinary citizen. The water for domestic use in Toronto has long been a source of danger and of great dissatisfaction to all connected with the city. Steps are now in progress to render the water supply absolutely safe, or as nearly so as human endeavor can bring about. But the works now under construction with this purpose in view will not be completed for some considerable period. In the meantime, the unpleasant and sometimes dangerous water is being treated with chloride of lime. This temporary expedient is said to be satisfactory except that on occasions it imparts a somewhat disagreeable taste to the water.

A Federal bill has just been introduced in the Parliament in Ottawa by Dr. Black, Liberal member for Hants, N. S., to permit physicians authorized to practice in any province to practice in all the other provinces of the Dominion. According to the Canada *Lancet*, December, it is understood that all the Provincial Governments and other interests have been consulted, and that the bill will not meet with any opposition. The bill may also, it is said, admit to practice physicians from any country in the British empire which extends a reciprocal privilege to the physicians of Canada.

Milk, in the same way as water, has for long been a much-discussed subject in Toronto. The general supply of milk of Toronto has been, and is, unsatisfactory. The situation has improved in this respect, and is likely to improve further and more rapidly. The present medical officer is an enthusiast on the milk question and is particularly interested in the pasteurization of milk. The Toronto Free Hospital for Consumptives, situated in Weston, some five miles from the city, was completely destroyed by fire on the night of December 1. The buildings, which were chiefly of wood, were consumed with great rapidity. Fortunately no lives were lost, although one patient succumbed to exposure and shock. The value of the buildings was not nearly covered by insurance. There were ninety-two in-patients at the time of the outbreak, of which number forty were confined to their beds and unable to assist themselves. The patients were removed to King Edward Sanitarium, the building of which is placed a hundred yards or so from the burned hospital. The cause of the fire is not definitely known, but it originated in the basement of the main building. In addition to the buildings, which were mainly of wood, all the contents were destroyed. The loss is estimated at $100,000.

The school medical inspectors of Toronto are doing satisfactory work. There has been a good deal of contagious disease in the city and by reporting incipient cases its progress has been checked. Dr. Hastings is of the opinion that by inspection the number of cases reported has been reduced by one-half. As a result of the inspection of school children's mouths it has been discovered that a large percentage of these suffer from defective teeth.

Complaints have been frequent among the inhabitants of West Toronto that some of the abattoirs situated there emanated unpleasant odors. The matter is to be looked into.

Dr. Wilfrid T. Grenfell, the English medical missionary to the fishermen on the coast of Labrador, has been, it is said, in New York, on the invitation of Mr. George B. Cluett, to consult concerning plans for building a schooner which Mr. Cluett has offered to Dr. Grenfell. It will be used to convey supplies to the Grenfell missions from New York and Boston.

During the stay in England of the Queen's Own Regiment, of Toronto, several of the officers and men were attacked by typhoid fever. An investigation is now being made with regard to the outbreak, but no public statement will be made until the report of the investigating board has been made at Ottawa.

The Toronto city architect has issued a permit for the erection of the surgical wing of the proposed new General Hospital. This part of the institution, which will be three stories high, will cost $250,000.

It is stated that the cocaine habit is very prevalent in Montreal, and according to the Toronto *Evening Telegram* Dr. Rinnie, member of the Quebec Legislature for one of the city divisions, is now at work on a bill which he proposes to introduce during the coming session which will provide prohibitive penalties for dealers in drugs if they are detected in selling cocaine for other than the purposes which the bill will specify.

The Quebec provincial health authorities have admitted that smallpox exists in some districts of Quebec. On December 14 there was a case in the College at Leirs, and in Lake St. John district the cases are recorded as epidemic. Montreal was free from the disease.

It is proposed to make the addition to Grace Hospital, Toronto, of a ten-story fireproof building, with accommodation for 230 beds. The new building is to be of steel, concrete, and terra cotta, and it is expected will be completed in eighteen months.

Dr. Chas. A. Hodgetts, of Ottawa, medical adviser to the Canadian Conservation Commission, fell down the stairs in his house on October 31, fractured two ribs, and sustained severe contusions of the head.

On the night of November 4 the Brandon Asylum, Manitoba, was destroyed by fire. There were 600 inmates at the time of the outbreak, all of whom were quickly got out of the building.

A Biography of Charles Spon, M.D. C. G. Cumston.
A Case Resembling Myotonia Occurring in an Adult, Due to the *Trichina Spiralis*, with the Pathological Findings in the Muscles. I. H. Coriat.

Chronic Arthritis.—H. W. Marshall, as the result of several years' experience with arthritic patients, comes to the following conclusions: The causes of chronic arthritis are many, and arthritis must be considered a symptom of many diseases rather than an entity that is produced always by the same specific cause. Causes generally are common diseases of other organs, common infections, and ordinary defects of personal hygiene rather than obscure and rare diseases. The most severe deform-

ing types of arthritis that stubbornly resist treatment and the mildest kinds that are easily controlled and permanently cured have similar origins. They differ only in the degree of severity with which the underlying causes act. Arthritic disease in every stage may often be modified by treatment, sometimes only slightly, and sometimes to a great degree, permitting permanent cures not infrequently. The best period to initiate treatment is in the incipient and early stages before chronicity is established, although the later stages also must be attended to when the disease has progressed to that degree. Diagnosis and treatment of incipient and early arthritis depend upon thorough knowledge of physiological conditions that control health and normal activity of joints, and cures result when defects in these conditions can be recognized and remedied. Proper application of simple hygienic measures and correction of defective personal habits are the most adequate means of treatment in the early stages. Increased efficiency in treatment depends upon greater clearness in understanding of normal physiological conditions that control health of joints, and also upon increased skill in treating diseases of other organs and infections that act as causes; and such knowledge of physiology and increased skill in treatment should be strongly advocated as well as search for new methods and new causes, for obscure conditions generally may be explained more satisfactorily as confusing combinations of common causes than by assumption of unknown rare pathological processes. New methods for treatment of chronic arthritis are likely to consist of very dissimilar ones, special drugs, organ extracts, vaccines, and physical therapy applied to diseases of different organs and to infections; and better comprehension of physiological conditions governing the health of all organs may also be advantageously emphasized. Future advances in treatment of arthritis, as in pulmonary tuberculosis, appendicitis, and some other diseases, probably will be toward prevention of extensive pathological changes by early recognition of the disease, and treatments will tend to become comparatively simple ones that prove themselves to be efficacious in these incipient stages.

Radium Therapy.—L. Wickham describes the efficacy of this mode of treatment in the following conditions: carcinoma, leucoplakia, hypertrophied scars, angiomata, pigmentary nevi, hairy nevi, tuberculosis cutis, psoriasis, angiokeratoma, linear ichthyosis, several forms of dyskeratosis and hyperkeratosis, lichen planus, acne rosacea, rhinophyma, and certain types of papilloma. The author states that there can be no doubt of the power of radium to relieve congestion, and this ability and the alterative qualities of the emanations have proved of great service in relieving the pains of certain epitheliomata and carcinomata and of numerous keloids. Radium secured also relief in many cases of neuralgia, including that accompanying and that following herpes zoster, neuritis gonorrheal and rheumatic arthropathies and iritis, and other experimenters have gained frequent favorable results in the deeper-seated pains of gastritis, tabes dorsalis, and sciatica. Such favorable experiences led the author to try the effects of radium in the pruritic diseases of the skin, with decided success in the relief of pruritus ani, with and without accompanying hemorrhoids, pruritus vulvæ, neurodermatitis, lichenification, and chronic eczema. He accomplished these results by the use of rays of weak and medium penetration which seem to have a selective action on pruritus and produce their favorable results without concomitant inflammatory reaction.

Etiology of the Tabetic Bladder.—J. D. Barney concludes that the bladder is guarded by two sphincters, an internal of smooth fibers, and an external of striated fibers, of which each has its special power of resistance. The function of urination is controlled by branches from the hypogastric plexus (nervi erigentes). The detrusor muscle may contract reflexly without connection with the central nervous system. The urinary disorders of tabes are dependent on, (*a*) a disturbance in the transmission of sensory impulses from bladder, (*b*) incoordination of the muscles of micturition, (*c*) urinary infection.

Biography of Charles Spon, M. D.—C. G. Cumston contributes this chapter to the history of early medicine in describing the life of the French savant, who was born in 1609 and died in 1684.

Myotonia Due to Trichina Spiralis.—I. H. Coriat reports the case of a man seventy-one years of age in whom peculiar stiffness of the leg muscles interfered with his ability to walk. Small pieces of the calf muscles were excised and examined microscopically, revealing in the connective tissue encapsulated larvæ of the *Trichina spiralis*. This was therefore regarded as the cause of the pathological findings in the muscles. It is well known that the encysted larvæ of the parasite may remain in the muscle for years. The author's case showed the typical gastrointestinal disturbances as a premonitory symptom of the disease, and closely on this the peculiar muscular stiffness followed, resembling a genuine myotonia.

Magic and Medicine. J. Knott.

Eggs.—R. C. Rosenberger states that the industry of hatching chickens for Easter is the time a good many unfertilized eggs are removed from nests and incubators and put on the market as fresh eggs. In other words, eggs which do not hatch are thus marketed and are termed "heated eggs" or "spots." It can be seen at a glance, that if the so called heated or spot eggs contain putrefactive bacteria and if kept in a mixture for some time before disposing of them, poisonous products are generated which may cause symptoms of gastroenteritis and simulate very closely cases of meat poisoning. The most rapid and efficient method of determining strictly fresh eggs is by the candling process, but by an expert. Some eggs that are put on sale as fresh eggs open up apparently fresh, yet when the dish is slightly jarred the admixture of white and yolk is easily accomplished, which, with a perfectly fresh egg, is only accomplished after severe beating. The spot eggs do not uniformly give off an odor, but a mouldy egg does, as well as a black rot or an ordinary rotten egg.

Wassermann Reaction and 606.—T. MacRae offers the following tentative conclusions: The probability is that should 606 prove harmless future medication will combine 606 and mercury in selected cases. Perhaps a course of one, two, or more injections of 606 will be given, antedated and followed by mercury. No patient should be treated without previous Wassermann reaction, and each case should be followed in its course with the reaction repeated in reasonably short periods. Negative reactions after 606 should be followed over a similar length of time as with mercury; negative phases, the so called precocious reactions, must be ruled out. The certain small percentage of active tertiary cases with negative Wassermann reaction must have the indications for 606 treatment more clearly brought out. The demonstration of spirochetes in such cases is not always possible. In certain cases of obscure affections of the nervous system, giving a negative Wassermann reaction, but with antecedent history of lues,

clinical results have apparently justified the use of 606.

Regulation of Prostitution.—M. Glasgow states that regulation of the social evil has never in any form secured a permanent footing on American soil; it is a measure essentially foreign in its aspects and a byproduct of old world opinions on the question of woman's inferiority to man. It is the attenuated survival of this medieval opinion in foreign born men and the sons of foreign born men which permits the discrimination against the woman of loose morals in favor of the man who has less. The menace to society from the profligate man is even greater than it is from his paramour. To decrease prostitution one ought to have education in the physiology of sex in the public schools, and there should be public instruction for all interested besides, as in the case of tuberculosis. Economic conditions for women should be improved, so that they are not forced on the downward path by hunger. Recreation and amusements should be provided to which all may be safely admitted; better protection of women through legislation, and the enacting of laws providing for the punishment of those who knowingly communicate venereal disease; making the report of all communicable disease to the Health Department compulsory, with proper provision for treatment when necessary; laws providing for a certificate of health from every candidate for a marriage license of freedom from communicable disease; and, if the lawmakers would permit themselves to so lacerate the feelings of the male, requiring from every man who visits a brothel that he submit to a medical examination from one of his own sex, that he have his finger prints taken and his name recorded by health officials, either man or woman, and that he further submit to treatment if necessary. In a very short time every house of prostitution would be closed for lack of the pecuniary support which men and men only tax themselves and families to afford.

Rest, Exercise, and Food in Tuberculosis.—A. P. Francine states that there is no feature in the management of tuberculosis more important than the proper adaptation of rest and exercise to the individual patient. This is not only true of the earlier and active stages of the disease, but also of the later stages and the after cure. Fever, cough, night sweats, loss of weight, anemia, weakness—all indicate rest. The author emphasizes the use of properly regulated exercise during convalescence. The subject of food in the home treatment of tuberculosis resolves itself for practical consideration into a matter of domestic economies. Strictly speaking, it is a social and economic rather than a medical problem, though it concerns us very closely as physicians, and it is through us that the problem must be remedied, at least indirectly. For consumptives who are sufficiently well to do to set a good, wholesome table there is little advice needed. Practically all of the usual articles of diet may be eaten, provided they are properly cooked. But with the average type of consumptive among the poorer working classes the question of food becomes a very serious problem, and one which must absolutely be taken into account. It may be discussed conveniently under the following phases: 1. The cost of food. How can one feed properly a family on five or six dollars a week for food? 2. The choice and selection of foods among the poor and ignorant. 3. The preparation of the food. All these problems could be simplified if there existed, generally in connection with philanthropic agencies and particularly in connection with tuberculosis dispensaries, diet kitchens, where patients could be sent to learn how to economize in the choice and selection of food; could learn the simpler rules of cooking, could be instructed in the use of the fireless cooker, and its simple and inexpensive construction; and where the medical supervision of the physician could be supplemented by easily learned facts in regard to habits of eating.

Climate as a Curative Agent.—F. G. Byles presents the following tabulated summary: Climates are either stimulating, as Colorado, or high, dry, cool, clear or sedative, as Florida: low, moist, warm, cloudy. Physiological action of these are opposite and cases improved by one will be made worse by the other. Principal characteristics of any climate: Altitude, humidity, temperature, sunlight, character of soil, prevailing winds. Physiological action of altitude is due to less oxygen and less pressure. Causes: Increased depth of breathing, increased rate of breathing, increased chest expansion, increased elimination of carbon dioxide, increased number of red cells, increase in hemoglobin, increase in lymphocytes, increase in cell formation, decreased blood pressure. Effects all due to effort of Nature to compensate for lessened oxygen and lessened atmospheric pressure: Humidity, absolute and relative, depends on distance from ocean; mountain ranges; character of soil; temperature. Dry climate accounts for: Increased comfort in both summer and winter; increased action of the skin; increased diathermacy; increased sunshine; increased outdoor life; increased germicidal power of air and sunlight. Denver has fifty-two per cent. humidity; the Coast, Middle and Southern States about eighty-seven per cent. Temperature, metallic and sensible, lowered by distance from equator and altitude. Cool air invigorates respiration, digestion, nervous system, whole body, and inhibits germ life. Sunlight favors metabolism, elimination of waste products, action of nervous system, function of skin, destruction of bacteria, outdoor life. Prevailing winds and storms do harm when winds are chilling or contain much dust. Character of soil affects humidity; dust storms; drainage; drinking water; mosquitos, etc.

Therapeutics of Old Staphylococcus Vaccine.—B. R. LeRoy offers a report of an interesting study of the efficacy of the remedy, the simplicity of application, the freedom from all untoward sequences that follow the hypodermic use of the bacterins, and the rapidity with which the remedy works. The time of treatment required, as compared with the subcutaneous injections of the fresh bacterin, is much shorter and much more pleasant, items of considerable value.

Impetigo Contagiosa Transmitted by Machine Oil.—O. V. Huffman reports a brief history of an epidemic of impetigo contagiosa among the machinists of a local manufactory, in which the infection was traced to one individual who, while suffering from an infected finger discharging pus, was working at a machine from which the oil was collected and pumped into other machines, where other men were working.

Enteroptosis in Children.—W. J. Butler describes the "habitus enteroptoticus" as a condition which is regarded as a congenital and hereditary anomaly by those who have

specially written on the subject. While this condition is more frequently seen in females it is often seen in males. The individuals are slender, of frail bony structure, thin musculature, and have little adipose tissue. The chest is long and narrow with small upper and lower apertures. Occasionally it is broad but shallow. The lower ribs are more or less vertical in direction and the epigastric angle is narrow. A floating tenth rib is rare. The abdomen is usually flat, with ocasionally slight bulging below the umbilicus, while sometimes the lower part of the abdomen may be very prominent. In the first months of life of a healthy breast-fed infant there is rarely any suggestion of the enteroptotic habit. On the other hand in frail infants, suffering from various diseases of malnutrition, one often sees many of its characteristics. If it could be found that the habitus enteroptoticus had its origin in periods of malnutrition it would be an important matter for the etiology, but this has not been established. The author has examined from 300 to 400 children, the majority of them healthy, and gives the results. Fully 50 per cent of all children have a movable tenth rib. In late childhood, however, at the approach of puberty, fully one-third of the females and about one-sixth of the males exhibit the characteristic habitus enteroptoticus. While no one sign can be depended on in children, the author is convinced from his observation that evidences of the enteroptotic habit are observable throughout childhood, but in a more pronounced form in late childhood, approaching and in the period of puberty.

Approximation of Wound Margins.—J. R. Eastman describes a running-loop suture which holds the margins together more firmly than any relaxation suture with which he is familiar; moreover, it will not cut out unless the pull be very great indeed, for here the tension is distributed over many points instead of two, as in the case of the ordinary relaxation sutures. In the case of the running-loop suture there are ten loops; therefore the tension is divided among ten points, and if several sutures of this character be used to reinforce the coaptation sutures, the wound margins, for example after a breast amputation, may be brought together under tension without subsequent separation and without cutting out of the sutures.

Tumor of Spinal Cord.—H. C. Moffitt and H. M. Sherman report the cae of a patient who, after being thrown from a buggy, suffered pain across the back just above the iliac crests which came on a year after the accident. A tumor at the left of the sixth dorsal spine was diagnosed, after failure of antisyphilitic treatment, and the spinal canal was opened. A small tumor 1.5 cm. by 0.76 cm. adherent to the dura was removed, which was found by microscopic examination to be a spindle-celled sarcoma. Improvement was rapid after the operation and gradual recovery was complete.

Compression of Renal Vessels.—D. N. Eisendrath and D. C. Strauss draw the following conclusions from a series of experiments on the rabbit: 1. Temporary compression of the renal vessels, if continued thirty minutes or less, causes very slight changes in the kidney. 2. Temporary compression of the renal vessels, if continued forty-five minutes, causes considerable parenchymatous degeneration and interstitial infiltration. 3. Temporary compression of the renal vessels, if continued one hour, an hour and a half, or two hours, causes marked permanent degenerative changes in parenchyma, as is evidenced by marked interstitial infiltration and extensive coagulation necrosis of the tubular epithelium; and, later, by the deposition of calcium in and about the destroyed tubular epithelium.

Etiology of Epithelioma.—A. E. Hertzler concludes that the formation of fibrin is the first step in the formation of connective tissue. Epithelium develops in the presence of fibrin only. In the artificial production of epithelium by Sudan III the first changes are in the subepithelial connective tissue. In *x*-ray cancer the epithelial development is preceded by changes in the connective tissue, which are identical with those which take place in the Sudan experiments. The change in the connective tissue in beginning epithelioma is tinctorially identical with that in the Sudan experiments and in *x*-ray cancer. The factor most constant in cancer etiology is chronic irritation. Chronic irritation produces the changes above enumerated. The sequence of phenomena above enumerated suggests as a working hypothesis that the etiology of cancer is associated with the lessened acidophilic properties of the connective tissue whereby it approaches fibrin in tinctorial reaction. The factors which produce the changes indicated in the connective tissues are the leucocytic properties of the blood and the fluid elements associated with them in reactive processes.

Drainage in Pancreatitis.—Le G. Guerry says that so far as he has been able to learn from the literature, and from what he has observed in the work of clinics, the operation of cholecystenterostomy in its relation to chronic or interstitial pancreatitis is not used as generally by surgeons in this country as it ought to be. A number of cases of chronic pancreatitis require more or less permanent drainage for a symptomatic and physiologic cure. The operation of cholecystotomy does not afford sufficiently durable drainage to allow the trouble to subside. Indeed, a point is reached when the pancreatitis becomes incurable, though the symptoms due to insufficient bile drainage may be relieved by operation. An interstitial pancreatitis lasting long enough involves the islands of Langerhans producing the so-called interacinous pancreatitis, with its resultant diabetes. The author reports a case in which the more thorough operation permanently relieved the patient and quotes from authorities supporting his point of view. He reports his own experience, which has been somewhat unusual and which has brought him to adopt the views here expressed.

Pathology of Gall-Bladder.—J. P. Runyan presents this paper, which was reported in MEDICAL RECORD, Vol. 77, page 1,110.

Diaphragmatic Hernia.—A. Bamberger reports a case of diaphragmatic hernia occurring ten years after the injury, a stab wound, which was its apparent cause. There were some symptoms of obstruction of the bowels, though not sufficient to positively diagnose the underlying condition, and some physicians had diagnosed the case as acute catarrhal appendicitis with paralytic ileus. An incision was made in the mid-line of the abdomen and the appendix found healthy, but marked distention of the cecum and ascending colon was present. The hole in the diaphragm was discovered in which a knuckle of the large intestine was strangulated and bound down by adhesions. The operation was completed by leaving this alone and anastomosing the proximal colon to the sigmoid. In spite of the severity of the condition the patient made a good recovery.

Industrial Accidents.—W. J. Manning suggests that the manufacturers, builders or agents of swiftly moving or power-driven machines should be made by law to place an indemnity bond with an approved surety company to the amount, say 5 or 10 per cent., of the total cost of the machine to run during the estimated life or period of usefulness of the mechanism, as shall be agreed on, which bond is to be drawn on by the employer or manufacturer for the purchase of safety devices, mechanical guards, etc., to be placed on the specific machine so covered. This would insure to the builder or agent the avoidance of responsibility and repetition of accidents and be also a security to the employer. The prevention of accidents thus obtained would be a great safeguard to the employee.

Wound of the Eye.—E. Armitage reports a case of extensive wound of the sclerotic and cornea with an ordinary knife, occurring in an 8-year-old boy with very unfavorable surroundings, exposure to dust, etc. The boy was treated under these conditions by absolute rest on the back, soft food to prevent mastication, and irrigations with bichloride of mercury solution and atropine instillations. The boy was taken to the physician's house daily, recumbent in a wagon. There were keratitis and iritis. These subsided and the wound healed satisfactorily, though the iris closed the pupil, leaving, however, some apertures through which good vision was obtained. A peculiar feature of the case was the development of a vein proceeding from the inner border of the upper eyelid along the median portion of the lid toward the outer canthus. The eye, apart from an anterior synechia and the scar, is normal in appearance. Atropine instillations are still being used, but the author does not intend to operate on the iris at present. He offers the case as an instance of the good effect of non-meddlesome management.

Cerebrospinal Fluid in a Case of Intraspinal Tumor.—C. M. Cooper states that the fluid withdrawn under a pressure of 160 mm. of water from a patient without fever, and with signs of a localized segmental lesion of the cord, had the following characters: Macroscopically, it was clear and of a yellowish-brown color, looking like the clear serous fluid that is aspirated from pleural or peritoneal effusions. On standing a well-marked cobweb coagulum formed. The Noguchi and Nonne globulin tests were strongly positive, thick precipitates occurring. The Wassermann reaction was negative in the fluid as in the blood. Microscopically, practically no cells were to be found either in the centrifugalized fluid or in the coagulum. No bacteria could be detected. The surgeon who later operated on the patient and the author came to the conclusion that they were dealing with a case of chronic compression of the cord, which was probably due to an intraspinal tumor.

Saphenous Varix.—A. H. Noehren reports a case of saphenous varix, simulating in appearance and situation a femoral hernia. He could find no similar case reported in the literature during the past three years, and while varicosities are frequent enough in the long saphenous vein, they are rare in this particular situation. To find such a tumor with impulse on coughing and easily reducible, as in this case, at once no longer reducible and tender in a patient with rising temperature, abdominal cramps, swollen tympanitic abdomen, and other symptoms of strangulated femoral hernia, was an unusual coincidence. The true condition was discovered only at operation.

Blood-Fixing Apparatus.—G. B. Lawson has devised an apparatus for accurately fixing blood stains by heat which he thinks avoids the disadvantages of the copper-plate method. By that method there is no way of determining the exact amount of heat used or regulating it. He uses an iron dish resting on an asbestos plate, under which is a gas burner. The iron dish is easily made by screwing a 2-inch nipple into a pipe cap. The dish is filled with petrolatum, into which is sunk a small slim copper cup, the end sticking out and just large enough to admit the glass slide easily. The bulb of the thermometer is held dipped in the petrolatum and registers the temperature. The slide may be introduced by using a small copper strip bent at an angle at the ends. With Ehrlich's stain the author has obtained the best results by heating to 280° F. for seven minutes. The apparatus has the disadvantage of requiring constant attention when in use, but that can be given by an untrained office assistant, and the slide is accurately heated.

Uterine Clamp and Retractor.—A. M. Taylor describes an improved instrument of this kind which he has devised.

Disorder of Medical Charity.—To be discussed later.

Medical Students and Medical Practitioners.—G. H. Colt delivered an address with this title before a society of medical students. He discussed the value of practical work, the imperfections of medical education, the overloading of the curriculum, suggested remedies, textbooks medical ethics, and prospects of success.

Treatment of Splenic Anemia.—G. A. Sutherland and F. F. Burghard state that this disease, or primary splenomegaly, is one almost always, if not invariably, fatal, whatever the medical treatment may be. The characteristics of this condition have been summed up by H. D. Rolleston as follows: 1. Anemia of the type usually spoken of as chlorotic—*i.e.* a diminution in the number of red corpuscles, with a diminished corpuscular value in the hemoglobin. 2. Absence of any leucocytosis, usually leucopenia. 3. Considerable splenic enlargement, which cannot be correlated with any other known cause, such as leukemia, syphilis, tuberculosis, malaria, or hepatic cirrhosis. 4. The prolonged nature of the disease. 5. The tendency to gastrointestinal hemorrhage from time to time. 6. The termination of the disease, if sufficiently prolonged, in hepatic cirrhosis with ascites (Banti's disease). The authors report two cases of splenic anemia in which splenectomy was performed. They discuss the pathology of splenic anemia only so far as it relates to the question of surgical treatment. There is no direct evidence of primary disease in any other tissue of the body than the spleen, and if a constitutional disease like malaria is present the case cannot be regarded as one of primary splenomegaly. Rolleston has suggested that "a chronic infective or toxic process has its headquarters in the spleen, and that the poisons produced there give rise in the first instance to endothelial hyperplasia and fibrosis of that organ, and later so inhibit blood formation as to produce anemia of the type usually regarded as chlorotic." Their experience does not support the view that there is an inhibition of blood formation. They believe that the spleen is actively engaged in the destruction of blood cells. The yellowish tinge in the skin and in the conjunctivæ is probably due to active hemolysis in the spleen—it is certainly not due to any disturbance of the liver function. As regards the ultimate result of the operation the authors give particulars in one case, the other having been so recently operated on. The first patient when seen at the age of 17½ years, four years after the operation, was a healthy girl without any signs of splenic anemia. This result may be contrasted with the fate of her sister, who died at the age of 13 years from progressive anemia and debility. In the published cases of this disease in which the spleen was successfully removed the ultimate result seems to have been a complete cure, records having been obtained up to eight years after operation. It is probable that the two factors present in their cases, the youth of the patient and the comparatively early stage of the affection, were of importance from the point of view of prognosis. While a preliminary course of medical treatment will naturally be adopted in all cases of splenic anemia, experience has shown that it is never curative, and if the diagnosis is clear treatment by splenectomy should not be unduly delayed.

Surgical Treatment of Cancer of the Vulva.—F. J. McCann states that it is a matter of common knowledge that the ultimate results of operations for vulvar carcinoma hitherto published are unsatisfactory, both local recurrence and recurrence in the inguinal and iliac glands being frequently observed. He believes the unsatisfactory results are due to the operations which are advised and practised for this disease either being incomplete or only employed when the disease is already advanced. Improved results will be obtained by the employment of a complete operation in the early stages of the disease. A nodule or a suspicious ulcer on a labium is not difficult to recognize, but what is of greater importance is to recognize and to treat the precancerous stages. Leucoplakial patches occur on the labia and precede the development of cancer, bearing a similar relationship to the disease in this situation as they do to cancer of the tongue. They are also commonly associated with a labial carcinoma, and it is absolutely necessary that they should be freely excised, for recurrence will certainly take place where such patches are situated.

Value of Vaccination and Revaccination.—F. M. Sandwith summarizes the following facts which prove the value of vaccination. There has been a marked fall in the mortality from smallpox in all countries dating from the time of introduction of vaccination. The vaccinated suffer much less from smallpox than the unvaccinated. Medical men, for instance, have a well-proved immunity, though in scarlet fever, against which doctors have no special protection, the statistics show that 59 per 1,000,000 die, as against 16 per 1,000 000, of the general population. The age-incidence of smallpox is quite different since the introduction of vaccination. Formerly most children took it, and in Gloucester, where 85 per cent. of the children were unvaccinated, 64 per cent. of the patients in the smallpox epidemic of 1898 were children under ten years of age. To-day, where infantile vaccination is thoroughly carried out, most of the patients are adults; for instance, in Glasgow in 1900 only 5.5 per cent. of 1730 smallpox cases were under the age of ten, and of these children two-thirds had never been vaccinated. The vaccinated, even if not efficiently protected by revaccination, have a much lower death-rate when attacked by smallpox than the unvaccinated. Systematic successful revaccination protects from smallpox. The German Government in 1874 made vaccination obligatory during the first year of life and revaccination at puberty. Since 1875 there have been no epidemics of smallpox in Germany, and the disease there is almost extinct. It is frequently introduced by foreigners, particularly on the Russian and Austrian frontiers, but it can find no resting place. In Prussia, where the population has been steadily increasing from 35 to 38 millions, the smallpox deaths for six years have varied from 10 to 41, being an average of considerably less than 1 per 1,000,000. This figure compares well with the year 1872, when 2,700 Prussians per 1,000,000 died from smallpox. In many smallpox hospitals it has been necessary to keep healthy children for weeks in the wards while their mothers underwent the disease; the children remained healthy, and were protected by one thing only—prompt vaccination.

Widal Reaction in a Fatal Case of Anemia.—P. Gully states that a case of pernicious anemia complicated by typhoid fever has probably never been recorded. He reports a case of pernicious anemia in which a positive Widal reaction was obtained in dilutions of 1 in 30 and 1 in 50 within one hour. He suggests the possibility that some cases of the severer anemias possess a blood serum abnormally charged with the substances which cause Eberth's bacilli to agglutinate. It would seem worth while to test the agglutinating power in similar cases. An exceptionally high agglutinating power would be additionally suggestive of an intestinal origin in these fatal cases, and might give some hint as to the nature of the organism causing pernicious anemia. It is observed that the whole of the illness only occupied seven weeks. Osler relates a case which was fatal on the tenth day.

Pituitary Extract in Obstetrics and Gynecology.—S. J. Aarons states that he has applied this drug in 70 cases altogether, but, as many of these were of a similar nature, for the sake of brevity they are not all particularized. For the purpose of contrasting this preparation with that of ergot and its allies he used the pituitary extract in a number of cases of normal labor and found that the uterus contracts better and more quickly and that the contraction remains for a longer period than when ergot or the other preparations have been employed. He has never used it, nor does he think it should be used, until after the completion of the third stage of labor, with the possible exception of certain cases of placenta previa. The only drawback at present to its general use is on the score of expense, but it is within the bounds of possibility that the active principle of the infundibular portion may be synthesized by chemists, when the cost will be materially reduced. He thinks that this drug is one for emergency cases, but the low blood pressure and general flabby condition of one patient warranted, in his opinion, a trial of pituitary extract. In this particular case there have been no deleterious effects whatever, such as arterial degeneration. These cases, however, are few and far between, but should one of a similar nature present itself he would be inclined to repeat the experiment. He can find no recorded instance of the employment of this drug in subinvolution of the uterus, and only suggests its use in this condition provided that the subinvolution is associated with a low blood pressure.

Rest and Movement in Tuberculosis. R. W. Philip.
"Eye" in Sport. R. W. Doyne.
The Influence of Diet Upon the Formation and Healing of Acute Ulcer of the Stomach. C. Bolton.
Thyroid Grafting and the Surgical Treatment of Exophthalmic Goiter. E. W. H. Groves and C. Joll.
Common Causes of Discharge from the Ears and Its Treatment. W. M. Mollison.

Rest and Movement in Tuberculosis.—R. W. Philip believes that as long as the tuberculous process is in active operation toxins are readily elaborated and passed freely to the muscles with resultant progressive dystrophy. This dystrophy affects not only the muscles of the trunk and extremities where it is evident, but affects likewise the heart muscle, the muscles of the vessels, and the muscles of other viscera. At this stage the indication for treatment is mainly rest. Rest has the double advantage of tending to stay the active local lesion and of limiting the output of energy by the dystrophic muscles. On the other hand, when the tuberculous lesion is less active or in process of arrest, and the production and carriage of toxins is correspondingly less abundant and rapid, the dystrophic muscles tend to recover themselves physiologically. Nothing repairs muscular tissues so certainly as natural movement. This is the motif and guide in the institution of regular activity. While natural repair is thus hastened by carefully adjusted movement, there is reason to suppose that at the same time a degree of relative immunization to tuberculosis is secured. It may be that under the influence of activity a process of autoinoculation is instituted. That is to say, by reason of the accelerated circulation a certain amount of toxin is carried through the system. The presence of the toxin stimulates the system to react, and to produce certain opposing elements or antibodies. The author states that indications for the reduction of activity will be found in increased rapidity of pulse-rate and irregular oscillation of temperature just above the normal line. Indications for the completer cessation

of active movement and a return to more or less complete rest are afforded by elevation of temperature over 99° F., a continuing pulse-rate of over 95 per minute with corresponding diminution of blood pressure, recurrent headache, especially at the end of the day, and an undue sense of fatigue.

"Eye" in Sport.—R. W. Doyne states that "eye" really exists in the brain. It is, in fact, a very compound thing, a subconscious brain judgment involving many other organs than the actual anatomical eyes. It involves knowledge, experience, very largely the sense of touch, and sometimes the sense of hearing or smell. This important fact is generally lost sight of. He discusses the rôle of this faculty in art, and in the games of billiards, cricket and tennis, and in shooting and fencing.

Diet and Gastric Ulcer.—C. Bolton concludes from his experiments that the theory with regard to the part played by the gastric juice in the production of gastric ulcer receives further confirmation, because ulceration is the more rapidly produced in proportion as the gastric juice is allowed a longer period of contact with the wall of the stomach. The epithelium grows over the base of an ulcer more rapidly when the animal is given a milk diet than when it is given a meat diet. In the case of a milk diet the base of a moderately sized ulcer is usually completely covered by the twentieth day, while in the case of a meat diet the same sized ulcer would in most cases be uncovered in the center at that time. Frequently, in the case of meat-fed animals, the ulcer is completely uncovered on the twentieth day, the granulation tissue of the base of the ulcer having become necrotic. Such an ulcer may be only one-fifth of the size of the original ulcer owing to the contraction of the fibrous tissue in the base, although healing has only commenced at the edge. In the treatment of a case of ulcer of the stomach the following principles should be observed: (a) During the early stages of the healing of acute ulcer the patient should be given a food which does not stay long in the stomach and which does not excite a copious flow of gastric juice. (b) The period of treatment in bed should be at least three weeks. (c) The starvation diet of the older physicians is not necessary, because the general nutrition suffers too much, and because ulcers heal well on some diet such as the above. (d) In the case of acute ulcers which are extending, or chronic ulcers, healing cannot be expected to occur in three weeks, because the ulcer must first be got into a suitable condition for healing, and then, owing to its size and thickness, the healing must take some weeks longer to be completed, so that the treatment in bed is to be conducted like that of simple acute ulcer, but extended over a period at least twice as long. (e) Since in many cases of gastric ulcer there is hyperacidity of the gastric juice, and when the gastric juice is acting destructively hyperacidity increases this destructive tendency, this high degree of acidity should be controlled by the administration of alkali. This is not so necessary in acute ulcer as in the more chronic forms, because the few estimations that have been made of the gastric secretion in acute ulcer show that it is not hyperacid, and the author has found experimentally that the effect of acute ulcer is to diminish the secretion in the early stages, and that the latter becomes normal as the ulcer heals.

Thyroid Grafting and Exophthalmic Goiter.—E. W. H. Groves and C. Joll report a case which illustrates very well the complexity of the various factors concerned in exophthalmic goiter. The following are its features of special interest: 1. The temporary improvement following partial thyroidectomy, which lasted only as long as the wound discharged. 2. The occurrence of tetany after subtotal thyroidectomy in which the parathyroids had apparently been preserved. 3. The cure of this tetany by thyroid medication. 4. The persistence of dyspnea and tachycardia in spite of subtotal thyroidectomy. 5. The occurrence of tetany of a functional type after thyroid grafting. 6. The cure of this form of tetany by hypnotic suggestion. 7. The great amelioration of the symptoms by thyroid grafting. 8. The occurrence of menstruation and coincident swelling of the grafts after thyroid transplantation. It is obvious both from a consideration of the author's case, together with the review of the literature of the subject, that the value of thyroid grafting is by no means settled, but enough has been said to encourage further work in this direction. It seems fairly certain that grafting can be successfully undertaken as far as the immediate vitality of the grafts is concerned. Further, that in recent cases of thyroid inadequacy a good functional result will accrue from this method. But time only can show what are the permanent results of this method.

Discharge from the Ears.—W. M. Mollison describes the causes and treatment of the various forms of discharge from the ears.

Berliner klinische Wochenschrift.

December 19, 1910.

Leprosy and Cancer.—A casual statement by I. Lewin, an American, to the effect that he had never seen cancer attack a leper inspired Söegaard, a Norwegian, to investigate the vast material of his country from this viewpoint. A partial explanation of the non-incidence of cancer in lepers is evident in advance, because leprosy attacks and destroys many before the cancer age. Again isolation of lepers may possibly secure them some immunity from cancer. Autopsies are seldom made on lepers who die at their homes—and these include about one-half of all cases. Some leprologists who inspect lepers outside of institutions, such as Hansen and Nielsen, have never seen evidences of cancer intra vitam in these subjects. Coming now to hospital material which has been subjected to autopsy, we find that in a material of 2,269 cases but 19 = 0.84 per cent. died of cancer. If we take only those subjects who were over 40 years of age—in round numbers one-half—we find 17 cancer deaths = 1.4 per cent. The general mortality from cancer in Norway is at present nearly 9 per cent. Therefore there is no question that the leper possesses a considerable degree of immunity to cancer. More statistics are doubtless in order. The author suggests that Iceland should next be investigated as to this kind of disease incidence.

Nerve Disturbances and 606.—Ehrlich writes briefly as to the great infrequency of neurotoxic influence of 606. There has been placed on record but one case in about 30,000 as far as the production of opticus atrophy is concerned. The patient had first been treated with other substances containing arsenic, so that the observation is incomplete. A few cases of disturbed hearing, temporary only, have been reported, and finally it has been stated that 606 has been known to attack the facialis. It has, therefore, been thought probable that 606 may have some faint selective action on the cranial nerves as a class, which would be in evidence should repeated injections be given. Ehrlich calls attention to the fact that most of the cranial nerves pass through bony foramina, where they are liable to attack in syphilitic periostitis. A few unsterilized spirochetes are able to cause such lesions, which have also been seen to occur after Hg-cures. There is no evidence whatever that 606 *per se* attacks the cranial nerves.

Nucleinate of Sodium in Paresis.—Donath writes further upon this subject, reporting five cases without much comment. The drug he believes to be a direct advance in the treatment of an almost incurable affection. Believing that the toxins of the disease persist in the blood, he began by subcutaneous infusion with 2 to 4 per cent. normal salt solution, with a view of flushing them out. Later he added the nucleinate of soda solution in the hope of oxi-

dizing the toxins. He injects the latter in increasing doses, 1 gram, the minimum, until a febrile reaction develops. Patient actually receives 50 c.cm. of a 2 per cent. solution for the first injection. The improvement in a series of cases seems undoubted, but, as usual, the possibility of recurrence cannot yet be excluded.

December 20, 1911.

Regeneration of Bone After a Single Injection of "606."—Therstappen of Bardenheuer's surgical clinic, briefly places a remarkable case on record. The lesion was caries of some toe phalanges and metatarsal bones of syphilitic origin. It was outlined before treatment by the *x*-ray. The patient denied any venereal infection and had always been well. But for the preceding four years he had had pains in the ball of the right foot. Quite recently there had been superadded an ulcerative affection of the toes of the left foot. On examination the left great toe was found swollen with a commencing ulceration. A similar ulcer was found on the second toe of the right foot. Despite these (isolated) lesions the feet appeared normal, and the patient himself was in good physical condition. The Röntgen ray showed a multiple caries, as already stated. Wassermann reaction positive. An injection of 606 was at once given, followed by one of morphine. A febrile reaction ensued. The ulcers at once improved, and abscesses evacuated themselves or were opened and treated on general symptoms. The new ulcers granulated. At no time did bone come away nor was it apparent on probing. The Wassermann reaction had now become negative, while a radiogram showed a remarkable regeneration of bone in the former carious localities. In other words the bones had healed up as soft parts may, without necrosis or caries. The case is believed to be unique.

Pupillary Disturbances of Dementia Precox.—Bumke, who has been at work on this subject for many years, gives some ultimate conclusions. The pupils in this affection are somewhat wider in average than in normal subjects, and dilate more readily and frequently. It cannot yet be claimed that the light reflex is permanently disturbed. In rare examples of katatonic stupor we find a rigid pupil, which may be either mydriatic or myotic, with or without change of form. Such findings are not peculiar to katatonia. The characteristic or pathognomonic pupillary anomaly of dementia precox is the absence of pupillary inquietude, the psycho reflex, and the reflex dilatation to sensible irritation, the light reflex remaining normal. This symtom, once understood, is always in evidence. It is frequent early in the disease, is usually present at the acme, and is invariably found at the end. It does not differentiate from certain organic brain diseases but has not yet been observed in the healthy, in functional pychoses, or in manic-depressive insanity.

On Mechanical Means of Checking Intestinal Hemorrhage.—Kelling discusses the entire subject of hemorrhage of the primæ viæ. Incidentally he touches on the question of inflation of the colon, in order to secure compression of other portions of the intestine. This is evidently the object of the author's study, although not specifically featured. In pregnancy, he states, the inflated colon readily compresses the stomach. With this as an entering wedge, he has inflated the colon repeatedly for hemorrhagic ulcer of the stomach. The air was injected slowly in a double bag, and the entrance of air controlled by percussion. The air was then allowed to escape and a sand-bag applied to the abdomen. The author's cases, three in number, recovered. Since death from hemorrhage often impends in gastric ulcer, some such resource is indicated. Competitive surgical procedures are not mentioned. It is understood that other hemostatics may be applied jointly.

Deutsche medizinische Wochenschrift.

December 22, 1910.

Diabetic Lipemia.—Klemperer states that in this condition the blood contains much cholesterin and lecithin, which originate from the subcutaneous fat. The fat of the viscera is unchanged. The lipoids enter the blood because of the breakup of the body cells. Once in the blood they attempt to regenerate the impaired cells. In brief, diabetic lipemia represents a mobilization of the cell lipoids to form new cells. This procedure enables us to understand certain results of therapy, particularly of severe cases. Albumin of the diet results in a splitting up of all albumin, which is accompanied by lipoid escape. Hence the observance by the patient of fasting days, vegetable days, and in general a low proteid diet goes far to antagonize the extreme tendency toward the breaking up of the cells.

Mouth Spirochetes and 606.—Gerber is continuing his work on this subject, which appears to be a promising one. In a former article he wrote of the action of the remedy on the saprophytes, so to speak. What we need chiefly, however, is the action of 606 in a pathogenic mouth spirochete. Such a one appears in the Plaut-Vincent angina, which is believed to be due to the joint action of a spirochete and a fusiform bacillus. The preponderance of influence in respect to these germs remains obscure, but Ehrlich cured at least one case of the angina with 606 in a few days. In ulcerated forms the spirochete of the disease is commonly associated with saprophytic mouth spirochetes and all vanish together under the injections. It is known that at times the resemblance between a specific ulcerous angina and a Plaut-Vincent angina is great. The latter has often been mistaken for the former. If we regard the Vincent spirochete as a quasi-normal denizen of the mouth, it is easy to see that mixed infection would be common. The discovery of the power of 606 over Vincent's angina would not be remarkable, for the latter may disappear without treatment and does not greatly menace other subjects. But it is significant that the remedy can promptly attack and destroy all spirochetes in the mouth. This is evidently not due to entrance of the remedy into the saliva, for, as the author says, it destroys the spirochetes in the depths of the tissue as well as on the surface.

Psychogenic Instability of the Blood Pressure.—Schrump states that before we come to a decision that a hypertonia is pathological we must make sure that it is not psychogenic. A rise of pressure of the latter origin affects chiefly the systolic pressure. The diastolic pressure does not appear to be under the influence of the mind, save in arteriosclerosis, where both forms of pressure may be modified alike. Psychic instability of blood tumors is almost constantly present in man, but is much more marked in the neuropath. While examining the pressure it becomes necessary to divert the patient's attention. As already intimated both the normal subject and the victim of pathological hypertonus are influenced mentally in this respect.

Experiences with 606.—Jadassohn concludes that the introduction of this substance into medicine marks an advance not only in syphilotherapy but in all therapy. Many authors appear to be combining 606 with Hg as a tentative method of early treatment. The author in cases of average severity gives a single injection of 606 and waits for developments. In any momentous case, early or late, lest 606 fail, the author would use both in combination. Educated persons may be allowed to choose for themselves after proper instruction. No remedy has ever received such a trial before subjecting it to the profession at large. The ideas expressed by the writer doubtless fairly represent the attitude which will be accepted by the majority of practitioners.

Book Reviews.

The Sources and Modes of Infection. By Charles V. Chapin, M.D., ScD., Superintendent of Health, Providence, R. I.; author of "Municipal Sanitation in the United States." First edition. New York: John Wiley & Sons. London: Chapman & Hall, Limited, 1910.

For nearly three decades head of the efficient health administration of Providence, R. I., the author is able to combine in this book the results of practical experience with those derived from his extensive studies. The completeness of the latter has already been foreshadowed in his authoritative work on "Municipal Sanitation," published in 1901. There is no subject in medicine in which recent researches have tended to revolutionize traditional beliefs as in that which deals with the sources and modes of infection. This book is an original exposition of these newer teachings, and in some respects the author takes a radical stand against deeply-rooted convictions. He emphasizes the importance of carriers as disseminators of such diseases as typhoid fever, diphtheria, and pneumonia, and cites a voluminous literature in support of this position. There is little evidence that any appreciable amount of the common infectious diseases arises in the external world, such as filth, and for this reason it is concluded that municipal sanitation and municipal cleansing are not synonymous terms or interchangeable functions. The danger to the community of missed cases and disease carriers is one that will require further investigation before its relative importance can be determined; nevertheless, it is a danger presenting to public health authorities the most perplexing problems in administration. The author believes that it is difficult to perceive any advantage in keeping such cases as persistent typhoid carriers in confinement, a practice that is more apt to place discredit on public health work. One may not agree with his statement that for every recognized case of diphtheria there is at least one sore throat which is also diphtheria, though unrecognized. The finding of diphtheria bacilli in a large proportion of cases of non-membranous angina does not stamp these cases as diphtheria any more than the presence of pneumococci in the throats of 50 per cent. of healthy individuals would justify one in regarding these as cases of pneumonia. In a most illuminating chapter the author discusses the growing evidence that isolation is of far less value than was believed a few years ago, that hospitalization in such diseases as scarlet fever and diphtheria cannot be expected to exterminate them, and that the effectiveness of isolation varies inversely as the number of missed cases and carriers. The author places considerable emphasis upon contact as the chief mode of infection, and states that there is no good epidemiological evidence that any diseases except those due to spore-forming bacteria are to any great extent transmitted by fomites. The best medical thought has been steadily restricting the supposed sphere of aerial transmission. Of striking interest is the statement that scarlet fever and diphtheria can be cared for in the same ward with other diseases without extension, if cleanliness be maintained and infection by contact avoided. The subjects of infection by food and drink and by insects are covered in a thorough manner. From its complete investigation of the statistical evidence pertaining to its theme, this work may be regarded as a reliable contribution to medical science.

A Treatise on Diseases of the Eye. By John Elmer Weeks, M.D., Professor of Ophthalmology in the University and Bellevue Hospital Medical College (Medical Department of New York University), Surgeon to the New York Eye and Ear Infirmary; Member of the American Ophthalmological Society; Honorary Member of the Royal Hungarian Medical Society of Budapest, etc. With 528 engravings and 25 full-page plates in colors. $6.00. Philadelphia and New York: Lea & Febiger, 1910.

The work by Dr. Weeks is something more than a treatise; it is an able and comprehensive dissertation on the diseases of the eye and their treatment. It would be a trite and obvious statement to say that a thorough knowledge of the eye and its affections, or even a fairly thorough knowledge, requires the study of a lifetime. There is no organ of the body, perhaps, which necessitates careful and painstaking investigation more than the eye, and therefore to write with authority on it is manifestly the task of the specialist. Dr. Weeks well represents this position and in this volume has lived up to these conditions. The path is cleared for a full understanding of the pathological processes discussed by a description of the embryology and anatomy of the eye and the principles of optics as well as of the chemical aspects of the subject. The work, however, is essentially practical in character, and the latest forms of treatment are dealt with in an interesting manner. The numerous engravings, colored and otherwise, admirably illustrate the text. It may be said that Dr. William Norwood Souter contributes the chapter on the general principles of optics. As a book of reference for the specialist and general practitioner Dr. Weeks' volume may be conscientiously recommended.

A Study of the After-Results of Abdominal Operations on the Pelvic Organs, Based on a series of 1,000 Consecutive Cases. By Arthur E. Giles, M.D., B.Sc. (Lond.), F.R.C.S. (Edin.), Surgeon to the Chelsea Hospital for Women; Gynecologist to the Prince of Wales' General Hospital, Tottenham. 10/6. London: Baillière, Tindall & Cox, 1910.

The statistical findings presented in Dr. Giles' book possess an unusual interest, because not merely the immediate, but the ultimate results of the operations are considered. The conclusions drawn, especially in the case of elective operations, are therefore of great importance and value. The general improvement in operative results during the period of the author's own activity is well shown by the change in mortality from 6.6 per cent. for the first 500 cases to 1.6 per cent. for the second 500. Dr. Giles has collected in his book the cases operated upon during the period of years from 1894 to 1909 and classifies the material as follows: salpingo-oophorectomy, double and single; abdominal hysterectomy alone and with adnexal operations; conservative operations for fibroids and operations for displacements. Among this series of 1,000 cases there were 41 deaths; from anemia (2), heart failure (8), shock (7), pneumonia (5), pulmonary embolism (2), secondary hemorrhage (2), intestinal obstruction (3), sepsis (9) and the remainder (3) from various causes. A chapter is devoted to each division of the classification already referred to, and there is a final chapter on abdominal operations in general, with certain very interesting conclusions. A considerable portion of the book is taken up with tables of the cases stated in detail. The presentation of statistical summaries of a large number of cases in a limited field of surgery by an operator of recognized industry and ability must serve a useful purpose, especially as the patients were so carefully followed and their condition so thoroughly studied. Very few contributions to medical literature have ever been issued similar to the work here referred to, and as such it will prove of great value not only for the statistical information presented but also as an example of the thorough and careful manner in which oprative results should be studied.

Treatise of Fistula in Ano, Hemorrhoids and Clysters. By John Arderne. From an early fifteenth century manuscript translation. Edited with introduction, notes, etc., by D'Arcy Power, F.R.C.S., Eng. Surgeon to and Lecturer on Surgery at St. Bartholomew's Hospital. London: Published for the Early English Text Society by Kegan Paul, Trench, Trübner & Co., Ltd., and by Henry Frowde, Oxford University Press, 1910.

John Arderne, who was born in 1307 and lived to be over seventy, represented the highest type of the surgeon of that period and was brought into contact with its most prominent personages. At one time he formed a part of the household of Henry Duke of Lancaster and later of that of John of Gaunt, and among his patients must have been numbered many of those whose names have come down to us in the pages of Froissart's Chronicles. It was one of the most dramatic periods of English history, and the records left by this intimate adviser of the great throw many interesting side lights on the life of his day. This reprinting of an early translation of his works by the Early English Text Society is therefore an important contribution not only to the annals of medicine but also to the social history of the English speaking people. Arderne was a pioneer in the radical treatment of anal fistula and substituted for the previous inefficient methods of dilatation with tents, application of caustics, and division of the tissues by tightly tied ligatures, an operation and instrumentarium fairly closely related to those in use at present. His dissertations cover a much wider field than is indicated by their titles, and are enlivened by many citations of cases and digressions concerning the relations of surgeons to each other and to their patients. The editor has contributed a very interesting introduction and also has freely annotated the text—all in so delightful a fashion that it is evident that, as he says, the work has been a labor of love. John of Arderne, seen through D'Arcy Powers' eyes, becomes a most attractive personage whose acquaintance should be made by all those to whom the history of medicine appeals.

Society Reports.

THE PRACTITIONERS' SOCIETY OF NEW YORK

235th Regular Meeting, Held December 2, 1910.

THE PRESIDENT, DR. H. M. BIGGS, IN THE CHAIR.

Unusual Case of Exostosis of the External Auditory Canal.—Dr. GORHAM BACON reported this case, and stated that the patient was a young man 20 years of age, who had had, six years ago, an attack of acute purulent otitis media caused by sea bathing. For three years he had had no treatment, and for the past three years had suffered from noises in the ear attended by an occasional purulent discharge. The physical examination was otherwise negative. In the left auditory canal a small round white tumor about the size of a pea blocked the canal almost completely, and only a very fine probe could be passed between the exostosis and the bony auditory canal. There was tenderness over the mastoid antrum. Respirations were 22, temperature 98.6° and pulse 96. Under anesthesia a curved incision was made behind the ear, and the auricle and canal wall were displaced forward over the tumor, which was found attached to the upper posterior quadrant. The pedicle was severed with a small chisel and the exostosis removed. The drum membrane was gone, and the middle ear was filled with granulations and cholesteatomatous material. The antrum was then opened and the necrosed bone and cholesteatomatous material removed. The usual radical operation was performed, by cutting away the upper portion of the bony canal wall and making one cavity of the antrum, attic, and midde ear. The temperature rose to 101.8° after the operation, but on the third day it fell to normal. There was a slight facial paralysis for a short time, but this finally disappeared and the patient made an excellent recovery. The interesting feature of this case was the absence of symptoms of pain, nausea, dizziness, or vertigo, especially when the tumor almost completely filled the canal, thus interfering with the proper drainage from the middle ear, and the danger, if it had been allowed to go on untreated, of meningitis or brain abscess.

Three Cases of Syphilitic Disease of the Choroid Treated by Sodium Cacodylate.—Dr. C. S. BULL said that a year previous he had seen an obstinate case treated by sodium dimethylarsenate, the so-called cacodylate, from which very favorable results were obtained, and he determined to use it at the very first opportunity. This came insterilized tubes containing 0.05 gram and 0.1 gram. This was very convenient for hypodermic injection. It was to be resorted to only in very obstinate cases. His first case was one of inherited syphilis, which was first seen when the patient was nine years of age. There was an extensive peripheral choroiditis in the atrophic stage, with myopia and astigmatism. There was normal vision with the proper glasses. In June, 1910, there was a sudden attack of choroiditis in the left eye with rapid loss of vision. Mercury and iodide of potassium were used both by inunction and hypodermically for three months without effect. On October 6 the vision was reduced to light perception, and the vitreous filled with exudation. One-tenth of a gram of sodium dimethylarsenate was injected into the buttock. The next day there was an improvement of vision. Two days later a second injection was given, followed by further improvement. A third injection was also given. On the ninth day after the first injection the vision had risen to 20/70, and the vitreous had become so clear that all the details of the fundus were visible. The second case was that of a man aged 32 years with an acquired syphilis. The initial lesion had occurred three years before, followed by numerous secondary symptoms. He had had two severe courses of mercury and iodide of potassium which were continued for fourteen months. Five months before Dr. Bull saw him he had an attack of iritis and choroiditis in both eyes, and the vision was reduced to the counting of fingers. The pupillary space was filled with exudation, but the adhesions of the iris were finally broken up by a three per cent. solution of atropin, and the vitreous was filled with opacities. Three injections of sodium dimethylarsenate were given at intervals of three days. The vitreous opacities almost completely disappeared and there was an improvement in the vision, and cessation of all pain. A fourth injection had been given a week later, which had continued the improvement, but the breath had a distinct garlic odor. The injections were then stopped. Dr. Bull said that three weeks after the first injection the vision was 20/30 plus, and that the choroid simply showed the site of the former exudations by white atrophic patches. The third was the case of a man aged 27 with acquired syphilis. The initial lesion had occurred five years before, with numerous skin and bone lesions and enlarged glands in the axilla and cervical region, and there had been an iritis in the right eye with very extensive and firm adhesions. The patient had had three prolonged treatments with mercury and iodide of potassium, including the mercurial baths. When Dr. Bull saw the patient he had a large gumma in the upper lid involving nearly one-half of the tarsus and another gumma of the sclera of the right eye, which had been of three months' duration. In all, five injections of one-tenth of a gram of sodium dimethylarsenate had been given. The gumma of the lid, which, after the first injection, had begun to soften, after the fourth injection had become entirely absorbed. The gumma of the sclera, Dr. Bull said, was the more obstinate, though it was smaller and softer. The infiltration of the ciliary body and iris had disappeared, and vision in both eyes was greatly improved.

Dr. KINNICUTT asked Dr. Bull how long ago he had treated them.

Dr. BULL replied that in the first case, which was acquired syphilis, there had been a sudden attack in June, and the treatment had been begun immediately and had been kept up until he saw him on the 6th of August. The physician in charge he knew to be most competent and thorough. In the third case the syphilis had been acquired. The trouble had begun five months before he saw the patient, and the antisyphilitic treatment had been kept up for five months. He saw this patient on the 28th of September. In the third case, he said, the syphilis had been acquired and there evidently had been an extra saturation of the syphilitic poison. The treatment had been kept up for a period of fourteen months and included mercurial baths. This patient, he said, he had seen on the 27th of October.

Dr. M. A. STARR said that he had used it very frequently for the past year and a half with no ill effects whatever, and that it was a very favored remedy in France. There was no remedy that acted so rapidly in general anemia and neurasthenia, for in both it had a remarkable stimulant and tonic effect, and in chronic functional diseases it had an extraordinary effect. Dr. Starr reported the case of a patient who, eighteen days ago, could hardly walk, but who that day had walked across the room without any difficulty. The disease was a mild myelitis of the lower cord. There was no syphilitic history. It was a case in which sodium cacodylate had a very remarkable effect on a functional nervous condition, resting on an organic basis.

Dr. KINNICUTT stated that he had used it in his hospital and private practice for a number of years, especially in cases of anemia, and that he had seen no evil results from it.

Dr. H. M. BIGGS said that he had employed it a great

deal for the past two or three years, and that in two instances there were small necrotic spots following injection.

Dr. C. L. Dana stated that he was always afraid to use it, and that he had seen two cases of optic neuritis.

Some Recent Experiences with the New Specific Remedy, Ehrlich 606.—By Dr. S. W. Lambert (see page 45).

Dr. M. A. Starr said that the subject was very interesting to the neurologist. There were two classes of cases in which the remedy had been used, first where there had been an active syphilitic lesion, such as a gummy exudation with symptoms of brain tumor, and secondly in tabes, paresis, and lateral sclerosis. In the latter class Ehrlich had recommended that it be *not* used. A week ago a patient had come into his clinic who had presented all the symptoms of locomotor ataxia, and who had suffered from an acute optic nerve atrophy. This man had stated to him that he had become almost totally blind within six weeks from the time that he had been first treated with 606 at another clinic. He had exhibited him to the students as illustrative of the danger in using 606 in tabes with any optic invasion, as there was no benefit to be derived in giving it in such an instance. In the case he mentioned the man had become totally blind in six weeks and had to be led around the city and to his clinic. He remarked that Ehrlich was opposed to giving it to tabetic patients.

Dr. W. G. Thompson spoke of a young man who had had very acute and general symptoms of the secondary stage of syphilis, and who had presented himself at the Bellevue clinic. His tongue was so swollen that it had protruded out of his mouth, as were the lymphatic glands in his neck. He had also a very marked roseola, and the patient had been very uncomfortable. Thirty-six hours after an injection of 606 had been given the patient was more comfortable, his tongue had gone down one-half in size, and after 48 hours the eruption had disappeared. At the expiration of two or three days the patient had recovered.

Dr. L. B. Bangs stated that the drug was experimental, and that he did not know what the future would bring forth. The Wassermann test was not a sufficient guide as to whether or not the physician should be content with one or two injections. He advised the administration of other forms of arsenic and cacodylate of sodium to be alternated with mercury. The experience gained so far, he said, was small, although the arsenic rendered the spirocheta immune. Ehrlich's 606, Dr. Bangs stated, was not sufficient, for there had been relapses of an acute nature. It was a doubtful experiment to let a patient go with only one injection of 606. Past experiences had shown that the administration of mercury was an antidote which must be kept up for years, and therefore, in his opinion, even if 606 had been administered, the mercurial treatment must be persisted in.

Dr. Joseph D. Bryant said that two months ago he had presented to the society a young lady who had suffered for a number of years from an infection which she had received by falling and striking her arm on a bread knife. The forearm at the site of injury developed an extensive inflammation and had caused a great deal of trouble. After months of treatment it had become necessary to amputate the arm because of the intractable nature of the trouble. This for a time had afforded relief, but the arm had to be amputated at the shoulder finally. After a time the other side, also in the arm, showed similar trouble, and extreme measures had been resorted to without effect. The arm tissue had become tense, painful and tender, and a periostitis had developed. The Wassermann test had been strong. The patient had been under a severe course of antisyphilitic treatment. 606 was administered four weeks ago. The patient had suffered much from the administration of the drug for a few days, but after that she had felt better. When Dr. Bryant examined her yesterday the induration on the arm was rapidly disappearing, and the pain and tenderness, which had caused her so much trouble had actually vanished, only slight tenderness remained. The interesting features in this case were the beginning of the disease in one arm, which had been relieved by amputation, and its recurrence in the opposite side and also attacking a lower limb, and later infection being relieved by the administration of 606. The patient had gained eight pounds in four weeks.

Dr. Kinnicutt spoke of the marvelous success attributed to 606 in the treatment of syphilis. Fourteen months only had elapsed since it was first used in human beings. In October of the present year Wechselmann reported its use by him in 1,100 syphilitic patients. In studying his paper the reader was especially impressed with its extraordinary effects in cases which had previously resisted every form of mercurial treatment. Dr. Kinnicutt reported the case of a lady who, two and a half years ago, had innocently contracted the disease. She had been subjected, under the advice and observation of Fournier, of Paris, to a very thorough mercurial treatment, and on coming to the United States had been referred to him. The secondary symptoms rapidly disappeared and a continued mercurial treatment with the later use of the iodides had been employed. No further evidence of the infection appeared until May, 1910, when (while still under treatment) a characteristic scaling syphilide of the palms appeared. She was seen by Dr. Kinnicutt six months later, when the lesion described was found to be present, in spite of energetic treatment in the interval. It involved the entire palm of one hand and quite one-half of the other palm. Dr. Fordyce kindly saw the patient by Dr. Kinnicutt's request and regarded the lesion as a typical chronic palmar syphilide. One-half gram of the alkaline solution of 606 was administered. Ten days later, when the patient went abroad, the lesion had markedly changed. The greater portion of the larger affected area on one palm had assumed the appearance of normal skin, leaving only a reddish periphery; the central portion of the lesion on the other palm showed a similar improvement. The patient was referred to her Paris physician. Much had yet to be learned in regard to the most efficient method of the administration of arsenobenzol, the dosage, the form, and finally as regards its repetition in the individual case. It was too soon to speak of its ultimate curative effects, but it might be safely said at the present moment that we possess in Erhlich's chemical compound an extraordinary agent for controlling the manifestations of the various stages of syphilis. Dr Kinnicutt further said that he had visited the Imperial Institute of Hygiene in Frankfort in the spring of 1910, where Ehrlich was conducting his experiments, and was kindly given every opportunity by him for observing the effects of arsenobenzol in rabbits and monkeys infected with syphilis. He came away profoundly impressed by the results obtained by Ehrlich. Ehrlich had pointed out the danger of the use of 606 when the optic nerve was affected. Wechselmann, however, in his paper stated that a toxic influence upon the optic sphere was not very probable, and that clinical observation seemed to favor the opinion that 606 can be used even in cases of diseased optic nerve. Dr. Kinnicutt said, inasmuch as it had been demonstrated that *some* aromatic arsenical derivatives produce in mice peculiar disturbances of coordination, "dancing mice," and Rötig had proved that these "dancing mice" showed degeneration of the vestibular nerve and some of them degeneration of the optic tract, he urged the acceptance of Erhlich's caution.

Dr. C. L. Dana stated that a short time ago a physician, who had recently been visiting in Berlin, told him that he had made inquiries in Germany regarding 606, and that the enthusiasm over it was more than its merits justified, and

that relapses and fatal accidents had occurred. Regarding the use of the drug in nervous diseases, he said that he had given it in a case of locomotor ataxia in its early stages, where the main symptom was the lightning pains. The patient did not take mercury well. At the end of three weeks, after the injection, he had come back feeling a little better and with the pains relieved. He did not think that that proved very much, however, for such favorable results were obtained with ordinary remedies. He spoke of two cases at the Neurological Institute; one after the administration of 606 had developed a fever and rash that was very like that of measles; the other was that of a man who had attempted to kill himself with "rough on rats," and he developed fever and a rash similar to that of scarlet fever. About six cases of tabes had been treated at the Neurological Institute with 606, with at least no bad results.

Dr. F. P. KINNICUTT said that it was of the utmost importance that all information of the effects on the optic nerve be brought out.

Dr. M. A. STARR said that Dr. Sachs had cabled to Ehrlich for information and that Ehrlich had replied that it was not to be used in tabes or paresis.

Dr. C. L. DANA said that it was supposed to kill the spirochetes and that if these were stamped out the disease ought not to progress.

Dr. J. W. BRANNAN stated that Dr. Dana's remarks reminded him of the similar impressions he had received when in Berlin three months ago. While passing through the children's wards of the Charité Hospital his attention was called by the physician in charge to a group of babies with congenital syphilis, some twenty-five or thirty in number, half of which were under mercurial treatment, and the other half under treatment by 606. The former were said to be doing much better than the latter. Many of the babies which had received 606 showed large, indurated, painful looking swellings. The opinion of the hospital staff in the children's service was distinctly unfavorable to the new treatment.

Dr. S. W. LAMBERT, in closing the discussion, said that the new idea in therapeutics was that it was possible to sterilize the human body of all disease germs at one blow. He said that the theory was to get the body saturated with the arsenic, and that the successful administration of the drug depended upon getting it absorbed in as large amounts and as rapidly as possible. This was the reason why it was given best in solution. In four of his five cases he had given it in suspension with very little reaction, but the fifth patient received it in solution in both nates. This patient had lain on his face for three days, when the local condition subsided. Since then the patient had been very comfortable.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 15, 1910.

DR. C. N. B. CAMAC IN THE CHAIR.

THE evening was devoted to reports from St. Vincent's Hospital (medical section) and the pathological laboratory of Mt. Sinai Hospital.

Aneurysm of the Descending Arch of the Thoracic Aorta.—Dr. SATTERLEE presented a man, forty-one years old. He gave a history of syphilis acquired about twenty years ago; for four years he was treated with mercury and iodide of potassium. He was markedly alcoholic up to ten years ago. Up to two years ago he gave a history of having chills and fever. He chewed and smoked nearly all the time. Two months ago he developed hoarseness and aphonia. He also had pain between the shoulder blades. Upon a throat examination there was found a paralysis of the left vocal cords. The man was fairly well nourished. His heart was markedly enlarged with dullness over the aortic area. The radial pulse was absent on the left side. There was a systolic bruit present. The *x*-ray picture revealed an aneurysm of the descending arch of the aorta.

A Case of Friedreich's Ataxia.—Dr. CHAS. E. NAMMACK presented this patient. In an experience of twenty three years at the New York Hospital and fifteen years at Bellevue Hospital Dr. Nammack said he had seen only two cases, one in each institution. The case he presented was the third he had encountered in nearly thirty years of active practice. The father and mother were alive and healthy. There was no history of tuberculosis, syphilis, or nervous affection. There was no history of any similar disease in any progenitor. When seven years old he helped his father and carried very heavy weights. In August, 1909, he was thrown from a horse, landing on his shoulder and broke his humerus. Since then he had been unable to do any work. In November, 1909, he noticed that his legs shook when he stood and that he shuffled his feet along when attempting to walk. He also had difficulty in expressing himself. The ataxia and difficulty with his speech continuing, he entered Bellevue Hospital in 1910. The ataxia and speech defects had increased and wasting of the calf muscles had occurred. There was weakness and pain in the legs, together with a shuffling gait. He slept well and had a good appetite. The pupils were irregular and unequal. They reacted to light and accommodation. The movements of the eyeball were equal. There was a slight nystagmus. There was no trouble with the sphincters. Romberg's sign was very marked. The Wassermann test was strongly positive. The patient was now on the mixed treatment. He had the "bird of prey" movement of the hand. Scoliosis was very marked because of the weakness of the back muscles. Later on he probably would develop talipes. It was important to diagnose this condition from the juvenile type of tabes, as well as from disseminated multiple sclerosis.

A Case of Hemorrhagic Pancreatitis.—Dr. CHARLES H. LEWIS and DR. J. H. LARKIN reported this case and demonstrated the specimen. The patient was thirty-seven years old, a bookmaker. He was well up to twelve years of age when he fell and sustained injuries of unknown character which rendered his health "delicate" for the following three years. When fifteen years old his general health seemed fully restored and for the next three years he excelled in athletic exercises. He then entered a bookbinding establishment; during the ensuing seventeen years his habits were exemplary, and his general health excellent. He then became a bookmaker, following the race horses, and frequented pool rooms. Then came a radical change in his habits. His general health, however, was comparatively good until one year prior to entering the hospital, when he had a convulsion which was diagnosed as of uremic origin. Four months later he had another convulsive seizure and again another one month later. Examination showed him to be a well nourished man, with no edema, but mentally sluggish and drowsy. He had some pain and tenderness over the middle right epigastrium. His twenty-four hours' urine was eighteen ounces, specific gravity was 1022, with a heavy cloud of albumin, many pus cells and granular casts; there was no sugar. He had no headache, and his vision was clear and the reflexes were normal. He remained in the hospital two weeks and after showing marked improvement in his condition he went to his home. About two and a half months later he was seized with his fourth convulsion. Three days later he staggered into the hospital. His face was pale and covered with cold perspiration. He was greatly prostrated, almost pulseless, his figure was bent and his hands were pressed into the left hypochondriac region, where he suffered excruciating pain. He had no

nausea or vomiting. He was admitted to the hospital and given morphine, enemas and laxatives. He slept well during the night. The next morning he felt comfortable with the exception of some slight discomfort in the lower epigastrium and left hypochondrium. About 8 o'clock A. M. he was seized with a sharp pain over the affected region; this was immediately followed by a clonic convulsion, then a spasm, and death in about twenty minutes. No examination of the stools had been made. Death was looked upon as due to pyelonephritis which he undoubtedly had, but he had other things as well. The clinical point of interest was the etiological connection between the convulsions, the lesions of the kidneys, and the pancreas. It was reasonably certain that the final convulsion, followed by speedy death, was due to the apoplexy of the pancreas; but it by no means followed that the four previous convulsions were not induced wholly or in part by the defective renal functions.

Dr. J. H. Larkin said that there was no doubt but that this was a case of pancreatic apoplexy; it represented one of the peculiar types, a very irregular form of pancreatic lesion often associated with syphilis. This patient presented all the appearances post mortem of a general arteriosclerosis and endarteritis. The specimen which Dr. Larkin demonstrated presented the different pathological features described by the earlier writers. There was a stone occluding the ampulla, causing a hemorrhagic condition in the pancreas itself. He had performed a number of autopsies during the past twelve years and among them he had met with but twenty-seven of these cases, and in not one case was the diagnosis made ante mortem. The spleen, pancreas and duodenum were all intact, but there was beautifully shown this apoplectic clot. There was a chronic interstitial pancreatitis.

Dr. Haven Emerson reported a similar case. The patient was brought to the hospital and appeared to be in perfect health, although he was "dead drunk." He awakened about 2 A.M. with pain in the epigastric region. For five days he was under observation. He had a leucocyte count of 15,000, which gradually came down. About five days after entering the hospital there developed a small tumor to the right of the midline, a little below the free border of the ribs. This was supposed to be a gall-bladder affection. The real diagnosis was not made before operation. Dr. Halsted said he had never seen a case diagnosed prior to operation. In this instance there was found a hemorrhagic cyst with fat necrosis. Dr. Emerson thought a better term to use would be acute fat necrosis with hemorrhage. This patient made a good recovery.

Treatment of Bone, Joint, and Gland Tuberculosis by Exposure to the Direct Rays of the Sun (Rollier's Method).—Dr. H. M. Biggs made this report. He gave a brief description of this unique institution at Geneva, Switzerland, where they treated bone, joint and gland tuberculosis at an altitude of 4,500 feet. Seven years have passed since Rollier established this clinic. The method employed consisted in the use of open galleries where the children were exposed to the direct rays of the sun during the entire period. These galleries had a southeast exposure. At first only those parts that were diseased were exposed for three or four days; but gradually the length of time of exposure was increased as well as the surface of the body until after a time the child was exposed while entirely naked. Pictures were presented showing these children as they were exposed summer and winter. Even in mid-winter they were absolutely naked in bed, with the temperature below freezing. These children did not suffer at all on account of these exposures. There was a remarkable growth of hair on their bodies. The results obtained at this clinic were most striking. As a result of this treatment there was almost invariably a complete restoration of function. Dr. Biggs thought that the good effects of this high altitude treatment were due to the ultra violet rays of the sun. This was, so far as he knew, the only institution in the world where such a plan of treatment was followed. The results obtained there were far in advance of any other method of treatment.

A Simplification of the Wassermann Test.—Dr. David J. Kaliski made this report. In the modification he said that every step in the technique was so controlled as to make the result of the analysis of the specimen of the blood as reliable as with the old method. He used active serum instead of the inactivated serum, but the dose used was not large enough to give non-specific fixation of the complement, a criticism that was frequently directed against the systems using active serum in dosage similar to the amount of inactivated serum used in the regular Wassermann test. The test differed from those using the active serum in that the native complement was not relied upon, but a small dose of fresh guinea-pig complement was added. A pure lipoid extract was used as antigen. A further simplication was afforded by the use of hemolytic amboceptor impregnated on filter paper. Anti-sheep amboceptor was easily prepared in great strength, could be readily impregnated on filter paper, and would retain its power with insignificant loss for a period of more than six months. Sheep corpuscles were used in the test. After the tubes had been incubated for the fixation of the complement in a water bath for thirty minutes, sheep's cells were added and the tubes were incubated again before the hemolytic amboceptor had been added. During the past four months he had examined over 400 cases of all sorts. In non-specific cases the test had never been positive when the Wassermann was negative. On the other hand, the test had proved at least as sensitive as the Wassermann, and in a number of cases of known syphilis it had been positive when the regular test was either negative or weakly positive. Dr. Kaliski recommended this test as a simple, accurate one for the detection of syphilis by means of a complement deviation.

Studies in Typho-Bacteriotropins.—Drs. A. A. Epstein and G. A. Fried presented a communication on the results obtained in their studies on phagocytosis of typhoid bacilli. An attempt was made to solve these problems. (1) The influence of bacteriotropic substances of normal and immune sera upon phagocytosis of the typhoid bacilli; (2) the influence of bacterial variation and virulence upon the phagocytosis of these bacilli. Human sera and leucocytes were used in all of the tests; for this purpose use was made of the blood of typhoid fever patients, taken at different stages of the disease and during convalescence. For the control tests, the blood of normal individuals was employed. The organism employed in the tests was from a stock culture of typhoid bacilli used in the laboratory. Subcultures of this organism were made daily on the following media: Plain agar, serum agar, 2 per cent. glucose serum agar, 2 per cent. glucose agar and plain agar, after one or more passages of the original organism through mice. The results obtained with suspension of the bacilli grown on the different media, both in respect to the number of organisms taken up by the individual cells and the percentage of phagocytes present, indicated in a striking manner the ready variability of the typhoid bacilli, when exposed to different cultural conditions, and the influence of such variations upon phagocytosis. This phenomenon was constant and could also be observed, although less definitely, in tests for spontaneous phagocytosis (phagocytosis occurring in suspensions of the bacilli and white blood corpuscles in salt solution). The resistance of the bacteria to phagocytosis increased progressively, as the cultural medium upon which the bacilli were grown approximated the condition existing in

the living host. In other words, the sugar present in the medium rendered the conditions more favorable to the growth of the organism; whereas the amount of the serum present in the medium at the same time compelled the organism to develop protective powers against its unfavorable influences. The result of this combination of circumstances exerted upon the bacterial organism was that it became more resistant to phagocytosis. The work led to the conclusion that the phagocytosis of typhoid bacilli depended less upon the nature and content of bacteriotropic substances of the serum than upon the resistance or virulence of the organism.

The Clinical and Pathological Aspect of Thrombo-Angiitis Obliterans.—Dr. Leo Buerger gave a review of the results of his studies on over eighty cases of what he designated as "thromboangiitis obliterans" and what had been so frequently mistaken for Raynaud's disease erythromalalgia, and other vasomotor phenomena. The Germans had described this disease under the name endarteritis obliterans. Beginning in most instances with indefinite pains in the sole of one foot, in the ankle or in the toes, the patients soon noticed that they were disturbed in their walk by the sudden onset of cramp-like sensations in the calf or elsewhere in the leg. After the lapse of weeks, months and even years, evidences of trophic disturbance make their appearance. Following the cutting of a nail, or without apparent cause, an abraded spot of hemorrhagic bleb, a pustule, or a dry, dead patch of skin developed near the tip of one of the toes or under a nail. Now the local pain became excruciating during the night as well as day, so that some of the sufferers begged for amputation of the affected part. It was during the first attack of trophic disorder that the physician usually noticed another characteristic symptom, namely, a peculiar blush of the toes and forepart of the foot, sometimes extending to the ankle or slightly above, when the limb was in a dependent position. Upon allowing the limb to hang down, the affected toe soon assumed a bright red hue which was seen to pass to the other toes and then up the back of the foot for a variable distance. The elevated extremity, on the contrary, readily became blanched. Sometimes the superficial ulcer would heal under conservative treatment and the patient would either recover perfectly or his symptoms would become chronic. At this period his limb would show scars left by previous ulcers; the dorsalis pedis and the posterior tibial artery usually failed to pulsate, and the ischemia in the elevated position and redness or "erythromelia" in the dependent position were regularly elicited. Sooner or later, however, an ulcer would give way to dry gangrene, and amputation would be the issue. Dr. Buerger presented eight cases of this disease demonstrating some of the clinical types. The form in which the symptoms of intermittent claudication were most prominent and in which there were the usual objective manifestations, with absence of pulsation in vessels, erythromelia, trophic disorder, ischemia in the elevated position, was demonstrated. The type characterized by pallor of the foot, coldness, cyanosis with little pain but a feeling of numbness when walking, and objectively with closure of the dorsalis pedis and posterior tibial arteries was also shown. Three of the patients presented the typical picture of the association of migrating phlebitis of the superficial vessels and the thrombotic affection of the deep vessels, namely, thromboangiitis obliterans. They were still in doubt as to the etiology of the disease. It was more than likely that some toxic substance might be responsible for the lesion. Smoking from an early age seemed to be common in most of the cases. Although lues had been held accountable by many writers, a series of twenty-nine cases whose blood was tested by the Wassermann reaction by Dr. Kaliski gave negative results. By means of lantern slides Dr. Buerger pointed out the usual microscopic lesions found in the veins and arteries. The pathological studies had been made by the reporter, and Miss Adèle Oppenheimer, on thirty-five amputated lower extremities and one upper extremity. The photomicrographs prepared by Dr. F. S. Manlebaum of the pathological laboratory of Mount Sinai Hospital illustrated the thrombotic process in this disease, showed that the occlusion of both arteries and veins was effected by red obturated thrombi which became organized, vascularized and canalized, that the process must be differentiated from arteriosclerosis, and was not to be regarded as an endarteritis obliterans. Thromboangiitis obliterans then was a clinical and pathological entity characterized by thrombotic occlusion of arteries alone or of arteries and veins, giving subjective manifestations, chief among which were pain and the peculiar symptoms of intermittent claudication, and presented objective phenomena, the most important of which were redness in the dependent position of the limb, marked blanching in the elevated position, evidences of arterial occlusion in the form of pulseless vessels, trophic disturbances of moderate extent and of even grave consequence, often terminating in gangrene of one or both lower extremities.

Investigations Concerning the Value of the Microscopical Examination of the Blood for Bacteria.—Dr. G. A. Fried, Dr. A. Sophian and Dr. George Blumenthal presented this report. Their investigations were undertaken to determine, if possible, in what per cent. of the cases in which blood cultures were positive bacteria could be found by direct microscopical examination, and also to determine whether organisms were present microscopically in cases in which blood cultures were negative. Altogether 250 cases were studied. The method followed was a combination of those used by previous investigators. At the present time they drew the following conclusions: (1) Bacteria could be found microscopically in the blood of the large majority (97 per cent.) of the cases in which their presence had been demonstrated by blood culture. (2) In a number of the cases (12 in 132, about 9 per cent.) bacteria were demonstrated in the blood which had been found sterile by means of blood cultures taken according to the methods now in vogue in their laboratory. Further studies must be made to determine whether there was any error in their findings. (3) It was probable that in cases of sinus thrombosis and in cases of osteomyelitis, microscopical examination of the blood might be of service in coming to a more rapid conclusion as to the presence of a bacteriemia. (4) Unless all possible precautions were followed in regard to asepsis, and unless all fluids and stains were filtered, the method was unreliable. (5) Microscopical examination of the blood with all the methods that had been so far used was not of service in cases in which the presence of Gram-negative organisms was suspected. (6) Microscopical examination of sedimented bouillon cultures might be of value in making an earlier diagnosis in some cases of typhoid fever.

Dr. E. Libman said that when this study was first taken up there were two main things which they wanted to investigate. In the first place, they wanted to find out whether the blood was really free from bacteria in those cases in which the blood cultures were negative; in the second place, whether they could obtain earlier diagnostic results in some of the positive cases. It was apparent that in such a disease as pylephlebitis, for instance, it might be found that the blood culture was usually negative because there were only anaërobics in the blood and the same held true in other forms of infection; but up to the present time the results had been negative. The results of positive findings in the cases of rheumatism were rather surprising as all their blood cultures in this disease had been negative. It was very important that this study be continued to see whether any error had entered

into the findings or not. The positive result in one case of sinus thrombosis was exceedingly interesting, and if the method employed should prove reliable it might be possible in some cases to have a report on the blood within a few hours instead of waiting anywhere from eighteen to thirty-six hours. Their experience taught them that the positive findings in cases of sinus thrombosis, when carefully noted with the clinical evidence, were of the utmost diagnostic importance and were often of life-saving value, a conclusion which many of the otologists in New York had thus far refused to accept, but which they would, in his opinion, accept later on. It was unfortunate that the Gram-negative rods present in so many bloods, and even in normal bloods, interfered so much with the value of microscopical examination, but the method suggested in the paper by Drs. Fried and Sophian for studying typhoid cases might be of value in giving an early diagnosis. For instance, it was well known that it happened every year in all the large hospitals that some cases of typhoid fever were operated upon for mistaken diagnosis of appendicitis. In doubtful cases, if the Widal test was negative, one might be able within six or eight hours to know definitely whether the patient had typhoid fever, and unnecessary operations could at times be prevented.

The Pathological Anatomy of Cardiac Arrythmias.—Dr. Alfred Einstein Cohn presented this report, which he illustrated by means of the lantern. He took sections from the hearts of three patients that illustrated unusual types of lesions in the conducting system of hearts that showed irregular action. He also grouped together with them other lesions that could be shown or were thought to be responsible for these and other forms of the known arrhythmias. In speaking of the pathological anatomy of the arrhythmias he confined himself to the consideration of the heart muscle only, and more especially to that of the conduction system. To make the muscle itself responsible for all irregularities was a newer conception and meant that the older notion which in some vague way connected the occurrence of irregularities with valvular defects had been relegated to the heap of defunct medical theories. The pathological anatomy of the arrhythmias was still a vague subject. He called attention to the anatomy of the normal conduction system, and pointed out that the anatomical knowledge possessed just now made it vain to hold one-sidedly either to a myogenic or to a neurogenic theory of conduction and consequently of structures, for it was a demonstrated fact that the system contained both muscles and medullated and non-medullated nerves as well as ganglia; it was in fact a neuromuscular system. What relative rôle each of these components of this obviously complicated system played in normal and in abnormal physiology, either in conduction or regulation, was quite unknown. The location of all of the system could easily be followed out, however.

Contribution to the Statistics of Complete Traumatic Paralysis of the Brachial Plexus.—Francesco Trozzi gives the history of a case of intracoracoid dislocation of the humerus caused by a fall, striking on the shoulder. It was reduced after twenty-four hours in the hospital, but left behind a complete disability of the entire arm, accompanied by oculopupillary phenomena in the left eye. These phenomena are due to the lesion of the fibers of the cervical sympathetic which communicate with the brachial plexus by the first dorsal and seventh cervical nerves. Since all the muscles of the arm, forearm, and hand are affected in these cases it is evident that there must have been a pressure injury of the brachial plexus by the head of the humerus at the time of accident. There will be found complete degeneration reaction of the muscles of the arm, shoulder, and hand, and absence of reflexes. There are also trophic changes in the nails, absence of pain, touch, and muscular senses, vibratory, and position sense. There is narrowing of the palpebral fold, and of the pupil.—*Gazzetta Medica di Roma.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Wyoming State Board of Medical Examiners.

October 26, 27, and 28, 1910.

ANATOMY.

1. Give a careful description of the duodenum, stating length, caliber, and openings into it.
2. If the femoral artery were obstructed at the apex of Scarpa's triangle, through what channels would the blood flow to reach the tibial arteries?
3. Describe the structure of the knee joint.
4. Name the twelve pairs of cranial nerves.
5. Describe a hair follicle.
6. Give the course and relations of the ureters in the male; also female
7. Name five muscles of the back of the leg.
8. What tissues of the abdominal wall are divided in the operation for appendicitis at (*a*) McBurney's point, (*b*) over the rectus muscle?
9. Describe the course and distribution of the nerves of the palm of the hand.
10. What is connective tissue and where is it found?

PHYSIOLOGY.

1. Give the physiology of the ureter.
2. Describe the nervous mechanism of muscular contraction.
3. Describe the physiological properties of bile.
4. Describe the physiological differences between lymph and serum.
5. What is metabolism? How many kinds and what are the differences?
6. What is food? Classify and give functions.
7. Describe briefly nervous control of heart.
8. What are the principal physiological functions of the skin?
9. Describe the physiological function of the testes.
10. Differentiate between serous, mucous, and synovial membranes. Tell where each is found.

MATERIA MEDICA AND THERAPEUTICS.

1. Give antidotes of poisoning by belladonna, corrosive sublimate, carbolic acid.
2. What are the physiological actions and therapeutic uses of arsenic?
3. Give physiological action of strychnine. In poisonous doses how does death ensue?
4. What are expectorants? How classified? Differentiate between the classifications.
5. Name the principal purposes for which diuretics are used.
6. What is ergotism? Give physiological effects and therapeutic uses of ergot.
7. Name two principal counter-irritants. For what purposes are counter-irritants used and upon what rests the basis for their employment?
8. Write briefly concerning the methods of giving enteroclysis. What are the principal medicinal substances used and for what diseased conditions is enteroclysis indicated?
9. Give the physiological actions of ipecac and its therapeutic uses.
10. What are the principal causes for failure in the use of bacterial therapy?

CHEMISTRY AND TOXICOLOGY.

1. What is specific gravity? What is a urinometer? Give specific directions for its use.
2. Describe physical and chemical changes of substances. Give examples of each.
3. Define chemical symbols. For what are the following symbols? (*a*) Au; (*b*) Ag; (*c*) Fe; (*d*) As; (*e*) K; (*f*) Sb; (*g*) Zn; (*h*) Hg.
4. Write formula for (*a*) common salt; (*b*) hydrogen dioxide; (*c*) carbonic anhydride; (*e*) calcium sulphate; (*f*) boric acid.
5. Write about iron: Occurrence in nature, atomic weight, properties, and name several of the preparations used in medicine.
6. Write about alcohol: Its occurrence, formation, properties, and name some of the preparations used in medicine.
7. How is iodoform made and what are its properties?
8. Give symptoms, fatal period, fatal dose, and treatment of phosphorous poisoning.
9. Give symptoms, fatal period, fatal dose, and treatment of oxalic acid poisoning.
10. Give test for albumin; for sugar in urine.

PATHOLOGY AND BACTERIOLOGY.

1. Define anemia, hyperemia, leukemia, and leucopenia.
2. Name the intestinal lesions of typhoid fever and give pathology of each.
3. Differentiate between carcinoma and sarcoma and give the diagnostic pathology of each.
4. Describe method of making the Widal reaction.
5. How do bacteria multiply?
6. Name the principal characteristics that would be present in a suspected culture if it contained typhoid bacilli.
7. What is tuberculin?
8. What is the difference between an antitoxic serum and an anti-infectious serum?
9. Give pathology of scorbutus.
10. Give pathology of catarrhal appendicitis.

PHYSICAL DIAGNOSIS.

1. Make drawing of the anterior osseous chest wall; show outline of the heart and thoracic aorta beneath. Indicate points covering the mitral, tricuspid, aortic and pulmonary valves.
2. State the significance of prolonged expiration. Auscultation in such a case would probably disclose what adventitious sounds?
3. Why are the apices of the lungs usually first affected in pulmonary tuberculosis?
4. Define cyanosis and give the various causes.
5. Define tacycardia; give significance.
6. What are hæmic murmurs as applied to the heart and what is the cause?
7. Name and describe the essentially different sounds given by the thorax on percussion.
8. (*a*) What is the cause of the second or diastolic sound of the heart? (*b*) What is the Corrigan pulse? Give significance. (*c*) Define pulsus paradoxus, intermittent pulse, dierotic pulse, bigeminal and trigeminal pulse.
9. Differentiate ascites and tympanites.
10. Give physical signs and causes of general anasarca.

PRACTICE OF MEDICINE.

1. Define typhoid fever, rheumatism, appendicitis, and cretinism.
2. Name the principal infantile contagious diseases and outline your treatment for one disease.
3. Mention diet for child one and one-half years old as you would to mother or nurse that you were instructing.
4. What are the following skin diseases? Eczema, prurigo, lentigo, herpes, and urticaria.
5. Mention treatment for psoriasis, erysipelas, and ringworm.
6. What is mania, melancholia, dementia?
7. Describe epilepsy and give treatment.
8. Give symptoms and treatment of bronchopneumonia.
9. Give diagnosis and treatment of gastric dyspepsia.
10. What is chlorosis? Give treatment.

OBSTETRICS.

1. Describe briefly the female pelvis.
2. Give the successive changes that take place in the ovum after fecundation and during its passage to the uterus.
3. What is the umbilical cord and what are its uses?
4. Describe the fetal heart sounds, give their rate and state when and where they are best heard.
5. Write about morning sickness, as to when it occurs, how long it continues, cause and treatment.
6. What is eclampsia? Give treatment.
7. Name several causes of abortion.
8. Give treatment for inevitable abortion.
9. Give list of articles needed by the physician during labor.
10. What are the dangers of a breech presentation? Why? Give treatment.

GYNECOLOGY.

1. What is a caruncle of the urethra? Treatment?
2. Why is gonorrhea relatively a more grave disease in the female than in the male?
3. Is ventrofixation of the uterus ever justifiable? How is the operation performed.
4. Define plastic operations as applied to gynecology.
5. When would you use the curette? Give steps of the operation in detail.
6. Give physical signs of cancer of the uterus in the early stage. What laboratory aids to diagnosis, if any, would you resort to in confirming your physical signs?
7. Diagnosis, prognosis, and treatment of uterine fibroids.
8. Give in detail the method to be used in making an examination of the pelvis.
9. State size, weight, measurements, and location of normal virgin uterus.
10. Write about the menopause, and give significance of that period of a woman's life.

SURGERY.

1. Name the luxations of the shoulder joints. What symptoms are common to all shoulder luxations?
2. Give etiology and symptoms of intestinal obstruction.
3. How are hernias clinically divided? Give palliative treatment of reducible hernia.
4. How are amputations classified? What general considerations imperative to observe to insure successful amputation?
5. What are the general indications in the treatment of all wounds?
6. Describe the postoperative treatment of a case of gangrenous perforative appendicitis.
7. What are the general considerations as to the treatment of gunshot wounds?
8. Describe case of cellulitis of the hand and give treatment.
9. What is the cause of varicose veins? How would you treat them?
10. Differentiate between location of foreign body in trachea, larynx, and bronchus.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WYOMING STATE BOARD OF MEDICAL EXAMINERS.

October 26, 27, and 28, 1910.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 1065; or Gray's "Anatomy" (1908), page 1290.
2. Through (1) the external circumflex anastomosing with the superior articular branch of the popliteal and anterior tibial recurrent; (2) the profunda femoris anastomosing with superior articular branch of the popliteal; and (3) the comes nervi ischiadici anastomosing with the superior articular branch of the popliteal.
3. See Cunningham's "Anatomy" (1909), page 297; or Gray's "Anatomy" (1908), page 336.
4. The special names by which the twelve pairs of nerves are generally known are: 1. Olfactory. 2. Optic. 3. Motor oculi. 4. Trochlear or pathetic. 5. Trifacial. 6. Abducens. 7. Facial. 8. Auditory. 9. Glossopharyngeal. 10. Pneumogastric or Vagus. 11. Spinal accessory. 12. Hypoglossal.
5. See Cunningham's "Anatomy" (1909), page 776; or Gray's "Anatomy" (1908), page 1197.
6. See Cunningham's "Anatomy" (1909), page 1141; or Gray's "Anatomy" (1908), page 1435.
7. Gastrocnemius, soleus, plantaris, popliteus, and tibialis posticus.
8. (*a*) Skin; fascia; external oblique, internal oblique, and transversalis muscles, and peritoneum. (*b*) Skin, fascia, rectal sheath, rectus muscle, and peritoneum.
9. See Cunningham's "Anatomy" (1909), pages 628 and 630; or Gray's "Anatomy" (1908), pages 997 and 998.
10. "By the name of *connective tissues* we designate a variety of tissues which have in common with one another that they are developed from the same embryonic elements; that they all serve as supporting tissue or connecting substance for nervous, muscular, glandular, and vascular tissues; that they are capable of taking one another's place in the different classes of animals; that in the embryo and in the growing normal and morbid condition one may be changed into the other; that in the adult they gradually shade off one into the other; and that they yield allied chemical products."—(Klein's *Elements of Histology.*)

PHYSIOLOGY.

1. The function of the ureter is to convey the urine from the kidney to the bladder.
2. The motor nerve cells discharge impulses through the motor nerves into the muscles, as a result of which the latter contract.
3. *The functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

4. *Lymph* contains white blood cells and also more water than serum; *serum* is the liquid part of the blood after coagulation has taken place, and is practically the plasma without fibrin. *Lymph* conveys food and oxygen to the cells, aids in the absorption of fat, lubricates serous surfaces, helps in maintaining the composition of the blood, fills the ventricles of the brain. *Serum* has a globulicidal action, and so is protective.

5. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative, or constructive (anabolism), and (2) destructive (catabolism).

6. *Food* is material which, after being taken into the body, is capable of building up the body, of repairing tissue waste, and of supplying heat and energy. *Foods are classified* as:

I. Inorganic..	Water.	
	Salts.	
II. Organic...	Nitrogenous—Proteids.	
	Non-Nitrogenous.	Carbohydrates.
		Fats.

Function of proteids: Formation and repair of tissues and fluids of the body, regulation of the absorption and utilization of oxygen, formation of fats and carbohydrates, production of energy. *Function of carbohydrates:* Production of heat and energy and formation of fats. *Function of fats:* Supply of heat and energy, supply of fatty tissues, nutrition of nervous system. *Function of salts:* Support of bony skeleton, supply of HCl for digestion, regulation of nutrition and energy. *Function of water:* It enters into the composition of all the tissues and fluids of the body, it moistens the surfaces and membranes of the body, it keeps the fluids of the body at their proper degree of dilution, it removes waste matters, distributes and regulates body heat.

7. The *nerves which control the heart* are: (1) The pneumogastric nerve, which slows or inhibits the heart beats; (2) the sympathetic nerves, which accelerate or augment the beats; and (3) the intrinsic cardiac ganglia, which enable the heart to continue beating for some time after it is removed from the body.

8. The *functions of the skin* are: Protection, excretion, secretion, regulation of the body temperature, absorption, sensation, special sense of touch, respiration.

9. The *function of the testes* is to secrete the germinal cells and spermatozoa.

10. *Mucous membrane* lines those parts which communicate with the exterior of the body; it contains glands, basement membrane, connective tissue support, blood and nerve supply, and epithelium. *Found* in digestive, respiratory, and genitourinary tracts.

Serous membrane lines closed cavities (except peritoneum in the female); it contains a basement membrane and endothelial cells, but no glands. *Examples:* Pericardium, pleura, peritoneum, tunica vaginalis of testis, and meninges.

Synovial membrane is in connection with joint and tendons, and has no glands, but a basement membrane with connective tissue cells.

MATERIA MEDICA AND THERAPEUTICS.

1. *Antidote* for belladonna, tannin; for corrosive sublimate, milk or white of egg; for carbolic acid, alcohol or sodium sulphate.

2. ARSENIC. *Physiological action:* Escharotic; irritant, tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart. *Therapeutic uses:* In stomach disorders, bronchial and pulmonary affections, diabetes, diarrhea, anemia, and chlorosis, chorea, malaria, and chronic skin diseases.

3. STRYCHNINE. *Physiological action:* Strychnine is a bitter tonic, stimulates appetite, secretion, and digestion, increases peristalsis, stimulates the vasomotor centers, and so raises arterial tension, and stimulates both accelerator and inhibitory nerves of the heart. All the functions of the spinal cord are exalted by strychnine, reflex, motor, vasomotor, and sensory. Large doses cause dilated pupils, irregular and jerky respiration, increased reflexes. In *poisonous doses* death ensues from asphyxia.

4. EXPECTORANTS are remedies which modify the secretion from the laryngeal and bronchial mucous membrane, and promote its expulsion. They are *classified* as: (1) *Nauseating*, or *sedative*, which act mechanically, by producing emesis, or by increasing osmosis; they generally lower the blood pressure and increase the secretion. (2) *Stimulating*, which facilitate expectoration by stimulating the mucous membrane; they generally raise the blood pressure and lessen the secretion.

5. Diuretics are employed: (1) To remove excess of fluid from the tissues, as in dropsy; (2) to dilute the urine; (3) to promote the elimination of waste products or poisonous material from the blood, and (4) to maintain the action of the kidneys.

6. *Ergotism* is a diseased condition due to ergot taken in food made from meal contaminated with the fungus *Claviceps purpurea.*

Physiological action of ergot: It stimulates and causes contraction of involuntary muscle fibers, hence it is a vasoconstrictor, hemostatic, and oxytocic. It is also a cardiac sedative, it raises the blood pressure, it increases peristalsis, and is an emmenagogue. *Indications for the therapeutic application:* To promote uterine contractions during third stage of labor; fibroids, menorrhagia, postpartum hemorrhage. Some forms of amenorrhea and dysmenorrhea, dysentery, arterial hemorrhage, congestive headaches, laxity of sphincters, of bladder or rectum, hemorrhoids, aneurysm, diabetes, urinary incontinence, direct paralysis of the sphincter vesicæ, atonic spermatorrhea.

7. *Two counterirritants:* Cantharides and mustard. "The entire basis for the employment of counterirritation rests upon reflex action, or the conduction of a nervous impulse to a center, which, when so stimulated, sends out an impulse to the part of the body which is diseased. The use of counterirritation may be divided into four parts or purposes: The first is for affecting inflammations or congestions; the second for causing the absorption or removal of inflammatory deposits after true inflammation has ceased; while the third purpose is for the relief of pain; and the fourth for the effect which can be exercised upon the general system by blisters in systemic disease."—(Hare's *Practical Therapeutics.*)

8. "By *enteroclysis* is meant the irrigation of the colon with large quantities of water, the latter being either plain or medicated, hot or cold, according to the effect desired. It is practised for a number of purposes: To cleanse the colon; to bring remedies in direct contact with the lower bowel in diseased conditions; to raise or lower the body-temperature; to stimulate the heart in shock or collapse; to restore water to the blood in anhydremia; to promote renal secretion; to dilute poisonous substances that may be present in the blood; to check intestinal hemorrhage; and to relieve intussusception."—(Stevens' *Materia Medica.*)

For method and substances see French's "Practice of Medicine" (1910), pages 260 and 298.

9. IPECAC. *Physiologicol action:* Hemostatic, expectorant, emetic, stomachic, cholagogue, and diaphoretic. *Therapeutic uses:* As an emetic, to clear the respiratory passages, to relieve the stomach, in bronchitis, emphysema, dysentery, and jaundice, and as a piaphoretic in rheumatism.

10. *The principal causes for failure in the use of bacterial therapy*, are: (1) The virulence of the infecting organism cannot be measured; (2) the patient's resistance, as measured by the opsonic index, varies from day to day and at different times in the same day; (3) the dosage and periods of administration are uncertain; (4) the present means of standardizing are notoriously inadequate; (5) each antitoxic serum antagonizes only the toxin employed in its production, and has no effect on the organism which may have produced it, or on other organisms.

CHEMISTRY AND TOXICOLOGY.

1. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of the same volume of a substance taken as a standard (water, air, etc.), under like conditions of temperature and pressure. A *urinometer* is a form of hydrometer used for taking the specific gravity of urine. *To use the urinometer:* "The cylinder should be of the shape shown in the figure, without pouring lip, of such depth that the urinometer may be completely immersed, and of a diameter double that of the wide part of the urinometer. Hold the cylinder in an inclined position and pour into it urine to within 2 cm. of the top. Set it upright, float the urinometer in the urine, and add more urine until the level "heaps" above the rim of the cylinder. Now bring the eye to about the level of the top of the cylinder, and, seeing that the urinometer does not touch the wall of the cylinder, read off the specific gravity at the *highest* point where the liquid, drawn up by capillary attraction, cuts the graduation of the urinometer."—(Witthaus' *Urinalysis*, etc.)

2. A *physical change* is such a change as does not alter the composition of a substance; a *chemical change* does alter its composition.

"A bar of soft iron may be made to emit light when heated, or sound when caused to vibrate, or magnetism when under the influence of an electric current. Under the influences of these *physicol forces* the iron suffers no change in composition, and, on cessation of the action of the inciting force, the iron returns to its original condi-

tion. But if the iron be heated in an atmosphere of oxygen both the iron and a part of the oxygen disappear, and a new substance, a new chemical species, is produced, having properties of its own, different from those of either the iron or the oxygen. In this case there has been *chemical action,* causing change of composition, as the new substance contains both iron and oxygen. The result of such action is, moreover, permanent, and the new product continues to exist, until modified by some new manifestation of chemical action."—(Witthaus' *Manual of Chemistry.*)

3. *Chemical symbols* are signs by which the elements are represented in chemical writing; they are generally the first letter of its Latin name, sometimes followed by one of the other letters, and they denote *one atom of the element.* Au is the symbol of gold; Ag, of silver; Fe, of iron; As, of arsenic; K, of potassium; Sb, of antimony; Zn, of zinc; Hg, of mercury.

4. Common salt, NaCl; hydrogen dioxide, H_2O_2; carbonic anhydride, CO_2; calcium sulphate, $CaSO_4$; boric acid, H_3BO_3.

5. Iron *occurs* chiefly in combination, as oxides (Fe_2O_3 and Fe_3O_4), carbonate ($FeCO_3$), and sulphide (FeS_2); also in soils, clays, and mineral waters. *Atomic weight* is 56. *Properties:* Pure iron is a soft, white, crystalline substance; it is oxidized at a red heat, and in damp air it is changed into a hydrate and called rust. It is soluble in hydrochloric acid and in dilute nitric acid. *Preparations used in medicine:* Reduced iron, carbonate, acetate, chloride, hydrate, citrate, hypophosphite, oxide, phosphate, sulphate, and tartrate.

6. Alcohol is formed by splitting up of glucose (by yeast), when carbon dioxide and alcohol result: $C_6H_{12}O_6 = 2CO_2 + 2C_2H_5OH$. It is a thin, colorless liquid, with a sharp taste and a spirituous odor; it boils at about 175° F. and freezes at about —200° F.; it attracts moisture from the air. By oxidation (in varying degrees) it becomes an aldehyde, an organic acid, and carbon dioxide and water. In medicine absolute alcohol, dilute alcohol, and whisky, brandy, and wines are used.

7. Iodoform. *Preparation:* By heating alcohol, iodine, and potassium bicarbonate:
$C_2H_5OH + 2I_2 + 2KHCO_3 = 2KI + 3H_2O + 2CO_2 + 2CHI_3$.
Properties: A yellow, crystalline solid with a peculiar penetrating odor; insoluble in water. It contains nearly 97 per cent. of iodine.

8. *Symptoms of acute phosphorus poisoning:* "Eructation of gas having the odor of garlic. The mouth, when observed in the dark, is frequently faintly luminous (phosphorescent). After several hours pain in the throat, a sense of heat in the epigastrium, nausea, and vomiting. The vomited matters are sometimes bloody, and frequently luminous when agitated in the dark. The abdomen is tender, and there are diarrhea and colicky pains. After one or two days these symptoms cease, there remaining only pain in the back and limbs and a feeble pulse. Death sometimes occurs suddenly in from two to four days. Usually about the fourth day the patient becomes jaundiced, suffers from headache, insomnia, and retention of urine, rapidly becomes delirious and comatose, and dies."—(From Witthaus' *Essentials of Chemistry and Toxicology.*)
Fatal dose: The minimum fatal dose is not determined; it is small, being probably less than one grain. *Fatal period:* From a few hours to several days. *Treatment:* By an emetic or the stomach tube remove from the stomach all of the poison which has not been absorbed; then give old French oil of turpentine or potassium permanganate; the food must be free from fats and oils.

9. *Symptoms of poisoning by oxalic acid:* "The sour taste of the acid is rapidly followed by a burning pain, increasing in intensity, in the mouth, throat, and stomach, and persistent vomiting of a dark, 'coffee-ground' material. The pulse becomes small and imperceptible, and the patient dies in collapse, preceded frequently by convulsions, within half an hour. If the case be prolonged, swallowing becomes very difficult and painful; there are numbness and tingling of the skin; twitchings of the facial muscles; convulsions, frequently tetanic; delirium, and lumbar pain. Death occurs in some cases within three to ten minutes, sometimes almost immediately, and in some cases it is delayed for several days." *Treatment:* "Magnesia (magnesia usta) or slaked lime suspended in a small quantity of water, or mucilaginous liquid, should be given *as soon as possible.* If vomiting do not occur, and if the symptoms of corrosion be not marked, an emetic. The stomach pump should *not* be used, nor should the alkaline carbonates be depended upon as antidotes."—(Witthaus' *Essentials of Chemistry and Toxicology.*)
Fatal dose: Usually from half an ounce to an ounce; but one or two drams have occasionally proved fatal.

10. Test for *albumin:* The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered. The reaction is then observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.
Test for *sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

PATHOLOGY AND BACTERIOLOGY.

1. *Anemia* denotes a condition in which there is reduction of the quantity or quality of the blood (generally used with reference to the red corpuscles). *Hyperemia* denotes excessive blood in a part. *Leukemia* is a condition in which the white blood corpuscles are increased in number, and is accompanied by pathological changes in the spleen, lymphatic glands, and bone marrow. *Leukopenia* is a condition in which the number of white blood corpuscles in the peripheral circulation is below the normal.

2. See French's "Practice of Medicine" (1910), page 70; or Osler's "Practice of Medicine" (1909), page 65.

3. *Carcinoma* is apt to occur at a later age; is found in structures derived from the epiblast or hypoblast; possesses a fibrous stroma, in which are found both blood-vessels and lymphatics; metastasis is by the lymphatics.
Sarcoma is apt to occur earlier; is found in structures derived from the mesoblast; there is no stroma between the cells; the blood-vessels are in direct contact with the tumor cells; there are no lymphatics; metastasis is by the blood-vessels.

4. See French's "Practice of Medicine" (1910), page 1219; or Osler's "Practice of Medicine" (1909), page 94.

5. Bacteria multiply by fission. A bacterium about to divide seems to be larger than normal, and if it is a coccus it becomes more ovoid; changes occur first in the nucleus, and the bacterium just falls in two. It has been calculated that a single baterium could, by fission, produce two in one hour. Fortunately, they seldom obtain food enough to keep up this process for any length of time.

6. See French's "Practice of Medicine" (1910), page 68.

7. *Tuberculin* is a glycerin extract of cultures of the tubercle bacillus.

8. An *antitoxic serum* only neutralizes the toxic products of pathogenic bacteria; whereas an *antiinfectious serum* destroys the bacteria.

9. See French's "Practice of Medicine" (1910), page 543; or Osler's "Practice of Medicine" (1909), page 751.

10. See French's "Practice of Medicine" (1910), page 807.

PHYSICAL DIAGNOSIS.

1. See Cunningham's "Anatomy" (1909), page 1268; or Gray's "Anatomy" (1908), page 559.

2. *Prolonged expiration* may denote: Phthisis, asthma, or emphysema. Auscultation would probably disclose râles.

3. The apices of the lungs are usually first affected in pulmonary tuberculosis because: (1) The blood supply of that part is relatively poor, and (2) in that part of the lung expansion is poor.

4. *Cyanosis* is a bluish tint of the skin due to insufficient oxygenation of the blood. *Causes:* Foreign bodies in the air passages, asthma, bronchitis, mitral disease of the heart, malformation of heart, diphtheria, laryngitis, goiter, pleurisy, pneumonia, emphysema, pericarditis, hypertrophy of the right ventricle of heart, hypostatic congestion of lungs, thrombosis of pulmonary artery, various drugs and poisons, and several other conditions.

5. *Tachycardia* is undue rapidity of the heart's action. *It is found in:* Fevers, most valvular lesions of the heart, exophthalmic goiter, chlorosis, pernicious anemia, locomotor ataxia, phthisis, alcoholic and other excesses.

6. A *hemic murmur* is one that is not due to valvular disease; it is usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient. It denotes as a rule an impoverished condition of the blood.

7. The different sounds given on percussion of the thorax are: (1) *Exaggerated pulmonary resonance,* which consists in an increase in the intensity of the sound, the pitch being slightly lower, while the quality remains un-

changed. (2) *Dullness,* which consists in a diminution of pulmonary resonance; the intensity is diminished, the pitch raised, the duration shortened, and the quality hardened. (3) *Flatness* is a sound resembling that produced by percussing the thigh. (4) *Tympanic resonance,* which is marked by the absence of proper pulmonary quality in resonance, in intensity it exceeds normal pulmonary percussion, and is lower in pitch. (5) *Vesiculotympanitic resonance,* in which the resonance is both tympanitic and vesicular; it is lower pitched, but more intense than normal pulmonary resonance. (6) *Amphoric resonance* resembles the sound produced by flapping the cheeks when the mouth is closed and fully but not forcibly inflated. (7) *Cracked-pot resonance* resembles the sound produced by striking the hands, loosely folded across each other, against the knee, the contained air being suddenly forced out between the fingers.—(From Loomis' *Physical Diagnosis.*)

8. (*a*) The second sound of the heart is due to the vibration caused by the closing of the semilunar valves. (*b*) The *Corrigan pulse* is one that is characterized by a short but strong impulse which seems to collapse under the finger. It is significant of aortic regurgitation. (*c*) *Pulsus paradoxus* is a pulse which becomes small and feeble during inspiration; *Intermittent pulse* is one in which one or more beats are omitted; *Dicrotic pulse* is one in which the first impulse is quickly followed by a second and lesser wave; *Bigeminal pulse* is an irregular one in which the pulse beats occur in groups of twos; *Trigeminal pulse* is an irregular one in which the pulse beats occur in groups of threes.

9. In *ascites* the abdomen is enlarged, but the appearance and shape change according to the position of the patient; when lying down, the fluid falls into the flanks, and these latter bulge, and give a dull percussion note, while on the summit of the abdomen the percussion note is tympanic. Further, fluctuation may be elicited. In *tympanites* the abdomen is enlarged, but posture makes no change; there is no fluctuation, and a tympanitic note is obtained everywhere.

10. See French's "Practice of Medicine" (1910), page 889.

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), pages 65, 222, 805, and 563; or Osler's "Practice of Medicine" (1909), pages 57, 219, 512, and 768.

2. Measles, scarlet fever, whooping cough, chickenpox, smallpox, diphtheria. For treatment of diphtheria see French's "Practice of Medicine" (1910), page 195; or Osler's "Practice of Medicine" (1909), page 207.

3. The following is given by Starr as diet from the twelfth to the eighteenth month: 7 A.M., stale bread soaked in a breakfast cup of new milk. 10 A.M., milk, six ounces, and soda biscuit, or a thin slice of buttered bread. 2 P.M., beef tea, six ounces, bread, and a tablespoonful of rice and milk pudding. 6 P.M., same as first meal. 10 P.M., a tablespoonful of Mellin's food in eight ounces of milk. In alternation a lightly boiled egg with bread crumbs and six ounces of milk may be given at 7 A.M., and at 2 P.M. a mashed baked potato moistened with four tablespoonfuls of beef tea, two tablespoonfuls of junket.—(Thompson's *Proctical Dietetics.*)

4. "*Eczema* is a non-contagious inflammation of the skin, characterized by any or all of the results of inflammation, at once or in succession, such as erythema, papules, vesicles or pustules, accompanied by more or less infiltration and itching, terminating in a serous discharge, with the formation of crusts, or in desquamation."

"*Prurigo* is a rare chronic inflammatory disease occurring first in early childhood and lasting indefinitely, characterized by pinhead to lentil-seed-sized, pale, red papules appearing usually on the extensor surfaces of the extremities and accompanied by intense itching. The cause is unknown."

"*Lentigo* is a pigmentary deposit of the skin, characterized by irregularly shaped, pin-head or pea-sized, yellowish, brownish, or blackish spots occurring for the most part about the face and back of the hands."

"*Herpes* is an acute inflammation of the skin, characterized by the development of one or more groups of vesicles, filled with a clear serum, occurring for the most part about the face *(herpes facialis)* and genitalia *(herpes progenitalis).*"

"*Urticaria* is an inflammation of the skin characterized by the development of wheals of a whitish, pinkish, or reddish color, accompanied by stinging, pricking, and tingling sensations, often associated with febrile and gastric symptoms."—(From Hughes' *Practice of Medicine.*)

5. *The treatment of psoriasis* consists of the internal administration of arsenic, cod-liver oil, oil of copaiba, or potassium iodide, and the use of local applications. The scales should be removed by soap and water, alkaline baths, or oily substances. Ointments containing salicylic acid (3 per cent. to 10 per cent.), tar (℥ss to ℥ss of ointment), ichthyol (℥ss to ℥ss), chrysarobin (gr. 10-60 to ℥ss), ammoniated mercury (gr. 10-40 to ℥ss), etc., are very beneficial, and should be used after the scales have been removed."—(Gould and Pyle's *Pocket Cyclopedia.*)

For *erysipelas* see French's "Practice of Medicine" (1910), page 221; or Osler's "Practice of Medicine" (1909), page 213.

"The *treatment for ringworm (of the scalp)* consists in daily washing of the head with soap and hot water, epilation of diseased hairs, and the application of parasiticide ointments and lotions. Sulphur ointment (℥ss to ℥j), beta-naphthol ointment (℥ss to ℥j), and bichloride of mercury solution (gr. 1 to ℥j) are favorite local remedies."—(Gould and Pyle's *Pocket Cyclopedia.*)

6. In both *melancholia* and *mania* there is a general perversion of the mental faculties, but the former is usually accompanied with more or less depression, and the latter with more or less excitement.

Dementia is "a progressive general weakening of the mind, characterized by a loss of reasoning capacity, a diminution of feeling, a weakened volitional and inhibitory power, and failure of memory, associated with lack of the power of attention, interest, and curiosity, in varying degrees, in an individual previously possessed of these mental qualities."—(Hughes' *Practice of Medicine.*)

8. See French's "Practice of Medicine" (1910), page 688; or Osler's "Practice of Medicine" (1909), page 624.

9. See French's "Practice of Medicine" (1910), page 747; or Osler's "Practice of Medicine" (1909), page 457.

10. See French's "Practice of Medicine" (1910), page 521; or Osler's "Practice of Medicine" (1909), page 721.

OBSTETRICS.

1. See Williams' "Obstetrics" (1909), page 2; or Hirst's "Obstetrics" (1909), page 17.

2. See Williams' "Obstetrics" (1909), page 97; or Hirst's "Obstetrics" (1909), page 78.

3. See Williams' "Obstetrics" (1909), page 137; or Hirst's "Obstetrics" (1909), page 136.

4. See Williams' "Obstetrics" (1909), page 181; or Hirst's "Obstetrics" (1909), page 203.

5. See Williams' "Obstetrics" (1909), pages 189 and 508; or Hirst's "Obstetrics" (1909), pages 187 and 237. The *causes* are: (1) Reflex disturbance, due to rapid growth and excessive distention of the uterus; (2) disease or displacement of uterus, tubes, and ovaries; (3) disease of pelvis or gastrointestinal tract; (4) excessive sexual intercourse; (5) renal disease or disturbance.

6. *Eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. For *treatment* see Williams' "Obstetrics" (1909), page 541; or Hirst's "Obstetrics" (1909), page 635.

7. *The causes of abortion* may be briefly enumerated as follows: "(1) Any pathologic condition of the ovum, membranes, or placenta, such as apoplexies, cystic degeneration of the chorionic villi, and cellular infiltration of the placenta. (2) Certain general diseases of the mother, including syphilis, typhoid fever, the exanthemas, and conditions interfering with proper aeration of the blood, as pneumonia and valvular heart disease; various systemic poisons, as malaria, lead, and arsenic; certain blood diseases, as grave anemia and leukocythemia; various local conditions, such as metritis, salpingitis, and ovaritis, cystitis, appendicitis, and placenta prævia. (3) Diseases of the father, such as syphilis, phthisis, and nephritis, in which the spermatozoa are diseased or of lessened vitality. (4) Death of the fetus from any cause. (5) Traumatism, as from a fall, a blow, or a kick on the abdomen. (6) Spasmodic muscular action, as in chorea, uncontrollable vomiting or coughing, convulsions of any kind. (7) Reflex causes, as violent emotion or mental shock. When the uterus shows a tendency to contract under the slightest stimulus (irritable uterus), any trivial cause, such as a long walk, a hot bath, or even the sight of another woman in labor may result in abortion. (8) Criminal abortion, caused by the use of drugs, vaginal and uterine injections, and the introduction of an instrument into the uterus."—(Pyle's *Pocket Cyclopedia.*)

8. Williams' "Obstetrics" (1909), page 619; or Hirst's "Obstetrics" (1909), page 281.

9. Williams' "Obstetrics" (1909), pages 303 and 306; or Hirst's "Obstetrics" (1909), page 325.

10. Williams' "Obstetrics" (1909), page 289; or Hirst's "Obstetrics" (1909), page 424.

GYNECOLOGY.

1. *Urethral caruncle* is a small, red, fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

2. See Rose and Carless' "Surgery" (1908), page 140; or Da Costa's "Surgery" (1908), page 1169.

3. See Rose and Carless' "Surgery" (1908), page 1278.

4. *Plastic operations* in gynecology include " all operations for the repair of lacerations of the cervix and perineum, and of vaginal fistulæ; also certain operations on the vaginal walls, known as elytrorrhaphy, and numerous operations on the urethra, vulva, and anus."—(Dudley.)

5. CURETTAGE. *Indications:* For diagnosis, to remove pieces of retained placenta or decidua, endometritis, mucous polypi, hemorrhage, dysmenorrhea, endocervicitis. *Dangers:* Sepsis, perforation of uterus, hemorrhage, abortion, inflammation of uterus or adnexa. *Procedure:* All antiseptic and aseptic precautions are necessary, the patient should be in the dorsal position, the vagina is to be disinfected, and the cervical canal dilated; a speculum is introduced into the vagina and the cervix is drawn down with volsella; the uterine cavity is irrigated with creolin or lysol; a curette is inserted to the fundus and moved down to the internal os; the operator should begin at one cornu, and go in the same direction all around till he reaches the starting point, and if necessary repeat till no more spongy or hyperplastic tissue appears; the fundus should be scraped separately by moving the curette along it from side to side; in going toward the fundus no scraping should be done, and care must be taken not to perforate the uterus; should this happen no fluid must be injected; otherwise the uterus and vagina are again irrigated, and one or more strips of iodoform gauze are inserted into the cavity to act either as a hemostatic plug or as a drain, which is diminished with two days' interval and withdrawn on the sixth day. A hemostatic tampon should be placed in the vagina and withdrawn the following day. If any fever arises the tampon is at once removed and the vagina douched with antiseptic fluid every three hours. If not, the vagina is only swabbed with the same every day, and packed loosely with iodoform gauze. After the final removal of the gauze the antiseptic douche is given twice a day until there is no more discharge. The patient should remain in bed for a week.

6. See Rose and Carless' "Surgery" (1908), page 1285.

7. See Rose and Carless' "Surgery" (1908), page 1280; or Da Costa's "Surgery" (1908), page 311.

8. The patient should be free from corsets and constricting bands; the bladder and rectum should be empty. *External palpation:* The patient should be in the lithotomy position, on a suitable table or bed. The examiner stands on one side and palpates the lower abdomen to determine any enlargement of the uterus. *Vaginal touch:* The examiner separates the labia with the thumb and finger of one hand; and two fingers of the other hand well lubricated are introduced into the vagina. Pressure is made on the perineum until the posterior fornix is reached, when the palmar surfaces are turned forward and the size, position, and condition of the cervix are determined. Then with the palmar surface of the external hand gentle pressure is made on the abdomen and the two hands are approximated. Thus the size, consistency, and position of the uterus are determined. *Rectal examination:* In virgins and in some cases of extreme retroversion one finger is introduced into the rectum and with the other hand on the abdomen a more satisfactory bi-manual examination can be made. *Instrumental examination:* In the lithotomy position, by the use of a bi-valve, a tubular or Ferguson speculum, the condition of the cervix can be inspected. This is best accomplished in some cases by use of the Sims position and the Sims speculum. At the same time in rare and selected cases by steadying the anterior lip of the cervix with a bullet forceps the uterine sound may be passed to determine the size and position of the uterus.

9. *The virgin uterus* is about three inches long, about two inches wide at the upper part, and about one inch thick; it weighs about an ounce, or an ounce and a half. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments—broad ligaments, round ligaments, vesicouterine and rectouterine.

10. The *menopause* is the period when menstruation ceases. The following (from Dudley's "Gynecology") will explain why the menopause is a critical period in a woman's life: The symptoms of the menopause are referable to two stages: a stage of menstrual irregularity preceding the cessation of the menses, and a post-cessation stage of variable systemic disturbances. In normal or nearly normal cases the irregularities are not excessive; the systemic disturbances are slight. There is a period of unstable equilibrium. The woman may at times be unusually capricious and emotional; yet she passes through this physiological crisis with only a few minor disturbances. She may have the characteristic vasomotor flushes, perspiration, vertigo, somnolence, numbness, and faintness. The menstrual function ceases as it began, with marked symptoms referable to the nervous system. Irritability, apprehensiveness, hysteria, melancholia, and other psychic disturbances are common in the abnormal cases, and may be exaggerated. The menstrual deviations vary in wide limits. The flow may gradually decrease and come at lengthening intervals until it altogether ceases; it may occur at short intervals or become continuous; it may become so excessive as almost to amount to dangerous hemorrhage; or life may be jeopardized by a slow, continuous drain. There is an increased tendency to malignant disease of the uterus and breasts during this period. The excessive fear of this may prey injuriously on the mind of the woman.

SURGERY.

1. See Rose and Carless' "Surgery" (1908), page 620; or Da Costa's "Surgery" (1908), page 587.

2. See Rose and Carless' "Surgery" (1908), page 1110; or Da Costa's "Surgery" (1908), page 837.

3. Hernias are divided, *clinically*, into: Reducible, irreducible, incarcerated, inflamed, and strangulated. See Rose and Carless' "Surgery" (1908), page 1079; or Da Costa's "Surgery" (1908), page 974.

4. AMPUTATIONS ARE CLASSIFIED: I. *According to time:* (1) *Primary*, soon after the accident, as soon as the patient reacts from shock, and before the onset of fever or sepsis; (2) *Intermediate*, during fever but before suppuration develops; (3) *Secondary*, some time after the accident, and when suppuration has occurred.

II. ACCORDING TO THE SITUATION.

III. ACCORDING TO THE INCISION AND THE FLAP.

"*Characteristics of good amputation methods:* (1) Minimum sacrifice of healthy tissue; (2) best permanent bone covering; (3) small wound area; (4) good blood supply to stump; (5) favorably placed cicatrix; (6) efficient drainage; (7) simplicity of method; (8) vessels and muscles cut transversely; (9) possibility of getting satisfactory musculoperiosteal covering; (10) ease of exposing bone at saw-line; (11) ease of bringing soft parts together over bone without tension; (12) adjustability of artificial limb; (13) largest range of adaptability; (14) shapeliness of resulting stump; (15) rapidity of method."—(Bickham's *Operative Surgery*.)

9. See Rose and Carless' "Surgery" (1908), page 350; or Da Costa's "Surgery" (1908), page 351.

10. See Rose and Carless' "Surgery" (1908), page 905; or Da Costa's "Surgery" (1908), page 767.

New Ideas with Reference to Streptococci in the Puerperal State.—Fabre and Bourret bring forward new ideas with reference to the presence of streptococci in the lochia of women who have just been confined, and before they have been confined. They find by experiments made at the Obstetrical Hospital at Lyons that some perfectly healthy women hold in their vaginas streptococci that are capable of producing severe epidemics of puerperal fever; others having only a slight rise of temperature after labor are also carriers. These germs are in condition of full virulence, and may cause a severe epidemic in an obstetrical ward. As a means to early diagnosis one should cultivate the lochial discharge on a solid medium. One may get a fair idea of the virulence of the germs by the number and size of the colonies and the rapidity with which they appear.—*L'Obstetrique.*

MEMORIAL ADDRESS ON DOCTOR ROBERT KOCH.*

BY JOHN A. WYETH, M.D., LL.D.,

NEW YORK.

PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.

FELLOWS of the Academy of Medicine and Invited Guests: At the November meeting of the Council there was read from Dr. S. Adolphus Knopf a letter in which he asked the privilege of presenting to the academy a portrait of the late Dr. Robert Koch. In granting the request the Council selected this date for the presentation and directed me as the presiding officer to submit on this occasion a brief memorial.

It will of course be recognized that no brief memorial could do justice to the career of this great scientist, and I shall be able to give here no more than a bare epitome of the life and labors of an unselfish worker for the welfare of mankind, of one who for many of his most laborious and fruitful years was an Honorary Fellow of the New York Academy of Medicine.

For the synopsis of Dr. Koch's life I am indebted to his devoted pupil, our fellow-member, Dr. Knopf. Born in 1843, Dr. Koch graduated in medicine at Goettingen in 1866. While an undergraduate he gave promise of a more than ordinarily brilliant career—in fact before his diploma was awarded he received a prize for an original essay upon "The Nerve Ganglions of the Uterus." After graduating he served as interne in the hospitals of Hamburg, after which he began the practice of medicine. He improvised a laboratory of his own and devoted most of his time to research work rather than practice.

In 1876 Dr. Koch announced the discovery of the spores of the anthrax bacillus. In 1878 he published his "Researches in the Etiology of Surgical Infections," and in connection with Gaffky, in 1880, announced the discovery of the typhus bacillus, and in 1882 the discovery of the bacillus of tuberculosis. A year later (1883) his study of Asiatic cholera under the direction of the German government resulted in his discovery of the bacillus of that disease. In 1885 he was elected professor of hygiene at the University of Berlin and director of the Hygienic Institute, of which he was the founder.

In 1890 he became the head of the Imperial Institute for Infectious Diseases and in that same year discovered tuberculin, the importance of which as a diagnostic factor in tuberculosis is well known.

In 1897, upon the invitation of the British Government, he went to Africa to study the rinderpest and succeeded in discovering an effective immunization in that disease. In the same year (1897) Dr. Koch, as head of a committee of scientists appointed to study the plague of India, visited that country, which was then suffering from a widespread epidemic of the bubonic plague. Returning from India, he was sent to Africa to study the sleeping sickness.

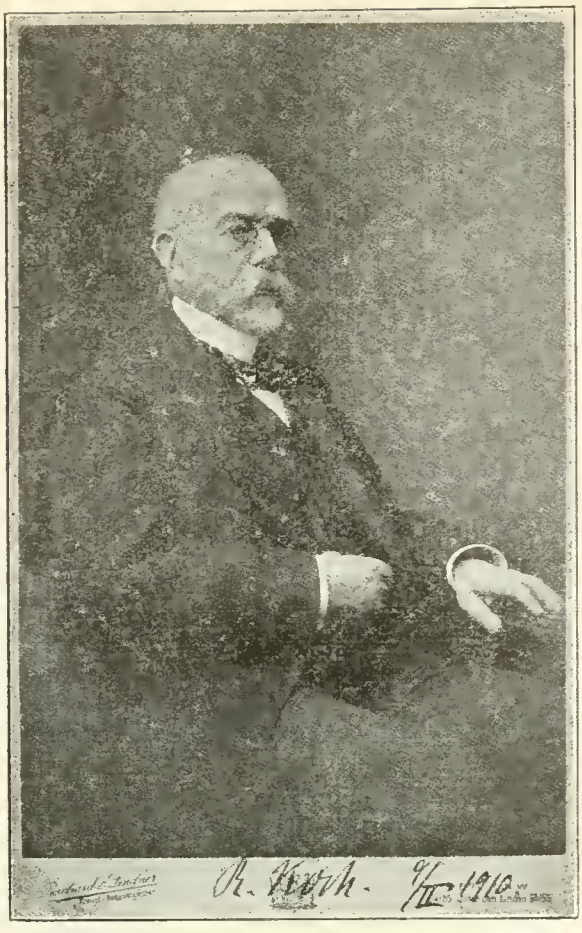
In 1901 at the British Congress of Tuberculosis Dr. Koch made the address which attracted such universal attention, emphasizing the difference in the morphology of the bacillus of human and bovine tuberculosis. In 1902 he inaugurated a systematic and successful campaign against typhus in German East Africa. In 1905 Dr. Koch was awarded the Nobel prize. In 1908 he visited the United States in his voyage around the world, and returning to his native land died on May 27, 1910.

Dr. Koch belonged to that rare group of men who exercised the double faculties of thought and labor. The larger number of men, and of our profession, work hard and faithfully but without being overgiven to thought. They are of that useful yet uninteresting class which in other times were known as hewers of wood and drawers of water. They are followers, not leaders, of men. In the parlance of another section of our country than this, they are content to trail along in the wake of the bellwether, guided by and keeping tread to the tinkling of his bell, and when he jumps over some great barrier to progress and alights in pastures new, in fresh and fertile fields, they, too, follow and are blindly fortunate.

Robert Koch was both worker and thinker, and he led men as a pioneer. In the world of research he was like our Daniel Boone; restless and unsatisfied with what had been achieved, he turned his back upon all about him and marched into the wilderness of the unknown. Over obstacles to the progress of research far more perplexing and disheartening than were the unbroken barriers of the Appalachian Range to the intrepid American, this brave, undaunted German, forgetting self in the enthusiasm of his devotion to science and humanity, with an untiring energy of mind and body which nothing but the incidents of disease and death could stay, marched on to one discovery after another, for which for all time men will rise up and call him blessed.

Mankind will not always worship as heroes the Cæsars and Napoleons, the great destroyers who covered the earth with ruin and buried beneath it countless lives sacrificed upon the altar of personal ambition. There shall yet dawn the higher and purer civilization when those whose genius and work have given life, health, and happiness to the world will be first in the heart of man. In this purer temple of fame, in the list with Jenner, Ephraim McDowell, Morton, Lister, Pasteur, Marion Sims, Walter Reed and Gorgas, there will be found the name of the immortal Robert Koch.

*Delivered December 15, 1910, at the Koch Memorial Meeting of the New York Academy of Medicine.



IN MEMORY OF ROBERT KOCH.*

By S. ADOLPHUS KNOPF, M.D.,
NEW YORK,
FELLOW OF THE NEW YORK ACADEMY OF MEDICINE.

Mr. President, Members of the Academy, and Invited Guests: For the honor of being permitted to present the portrait of the late Professor Robert Koch to the Academy of Medicine of New York I desire to express to the president, the council, and the other officers my grateful appreciation. The only claim I can advance for this privilege is that I am one of the thousands of humble disciples of the master of tuberculosis science and that he was an honorary fellow of this academy, to which it has been my privilege to belong as a member for over a decade.

The week beginning with December 11, the birthday of Robert Koch, has been selected by his German admirers as a most fitting time to honor his memory with appropriate exercises in Berlin and other medical centers. Hence it must be gratifying to all friends and admirers of Koch that the New York Academy has decided to do likewise and that this has been set apart to be a memorial evening. While I am sure that the New York academicians will feel that, in thus honoring a great physician and honorary fellow of the academy, they have but done their duty, nevertheless I think they will be pleased to hear of the grateful appreciation of this act on their part by the widow of the illustrious man. On November 26 Mrs. Koch wrote me: "I wish there was time so that I myself could be permitted to have the portrait of my late husband made here so that I could take it with me when I shall visit America some time after Christmas and present it to the Acadamy. I cannot tell you how deeply I appreciate that there will be in New York about the same time as in Berlin a memorial celebration in honor of my beloved husband."

Robert Koch's achievements as a master in bacteriological science, as a student of anthrax, cholera, typhus, plague, rinderpest, etc., have already been eloquently referred to in the eulogy pronounced by our distinguished president. Through the courtesy of Professor Wyeth I am permitted to say a few words on what the world owes to Robert Koch for his discovery of the tubercle bacillus and of tuberculin, and for the deep study he has made of the sociological problem of tuberculosis.

On the evening of March 24, 1882, before one of the largest gatherings of the Physiological Society of Berlin, in his paper "The Etiology of Tuberculosis," Koch announced the discovery of the tubercle bacillus. He did it modestly but so conclusively and with presentation of facts so beyond possible dispute that for the first time in the history of that society the paper, which was listened to in profound and respectful silence, was not discussed. The members looked expectantly to their veteran debator, the father of cellular pathology, the great immortal Virchow, but he, too, remained silent, overcome by this revelation made by a master mind in a masterly way. Prior to Koch's discovery we knew, of course, thanks to the labors of Villemin, Cohnheim, and others, of the contagious character of tuberculosis; but we did not know the factor of contagion, hence we did not know how to prevent the spread of the disease. All our present preventive measures are based upon the discovery that tuberculosis is caused by a bacillus found mainly in the pulmonary secretions, in involved tissues, and to a minor degree in other secretions of man and beast afflicted with the disease.

It has been statistically proven beyond a shadow of doubt that because of the knowledge acquired and the effective preventive measures inaugurated as a result of Koch's discovery of the presence of the bacillus in pulmonary secretions the death rate from tuberculosis has decreased nearly everywhere.

Because of this revelation made to us by Koch how many thousands of lives have not been saved annually from an untimely death since 1882? What economic gain has thus not been to the wealth of nations by the preservation of the lives of bread winners and useful citizens? What human sorrow and suffering have not been spared to untold numbers because Koch has shown how to prevent the spread of the disease so graphically described by our own Oliver Wendell Holmes as "the great white plague?"

Koch's experience with tuberculin as a therapeutic agent, as many of us remember, was painful in the extreme. Against his wishes the discovery of this product was prematurely announced as a specific in tuberculosis. The result of the use of so powerful a product in the hands of the inexperienced and its indiscriminate use in all cases was followed by the inevitable results. Since then, by the painstaking, careful and patient experiments of clinical observers all over the world, Koch's claims that tuberculin has a diagnostic and therapeutic value in certain cases have been verified and substantiated.

Of Koch's interest in the sociological aspect of tuberculosis comparatively little is known. Yet he was a most profound student of this side of the tuberculosis question. He firmly believed in the municipal control of tuberculosis. More than once

*Delivered at the Koch memorial meeting of the New York Academy of Medicine on the occasion of the presentation of a portrait, December 15, 1910.

did he express to me personally his gratification over the work inaugurated in New York by my esteemed friend and teacher, Professor Hermann M. Biggs. In his celebrated London address he pointed to New York's municipal control of tuberculosis as an example to be emulated everywhere.

Koch believed in popular education of the masses. My own humble labors in this direction have been aided by many an encouraging message from him. In writing to me on the subject a few months before his death (it was the last letter I received from him) he also paid a graceful compliment to the American people. His words were as follows: "Popular works on tuberculosis are destined to play an important part in the enlightenment of the people and the American people seem to me particularly susceptible to such education."

The master honored me in this letter by presenting me with his last photograph, signed by himself and dated February 9, 1910. The portrait before you is an enlarged reproduction of the photograph in my possession.

Koch's last word on tuberculosis was an interesting lecture delivered before the Academy of Science in Berlin on "The Epidemiology of Tuberculosis." From it we learn that Koch saw in the ample provision of hospitals and sanatoria, the improving of the working, living, and particularly the sleeping quarters of the masses, the greatest and most important factors tending to reduce the mortality of tuberculosis.

Koch's final illness was a painful one (arteriosclerosis). Yet he was a quiet, uncomplaining, and obedient patient, following his physician's directions implicitly and watching with stoic tranquillity the progress of his disease. As a sanitarian Koch was a believer in cremation, and in accordance with his wishes his body was incinerated at the crematory of Baden Baden. His funeral was private; no flowers ornamented the plain coffin, yet the whole civilized world mourned at his bier.

What a debt the world at large owes to this master mind for what he has done toward the understanding, prevention and cure of this one disease alone is hard to realize even at this moment. His humble disciples and mankind at large are only now beginning to reap what he has sown.

Robert Koch himself looked upon his great achievements as nothing extraordinary. Those of us who were privileged to listen to him when he was the guest of honor of the German Medical Society of this city will never forget those inspiring yet so modest words with which he referred to his epoch-making discoveries. He said: "I have done nothing else than what you are doing every day. I have worked as hard as I could and have fulfilled my duty and obligation. If the success really was greater than is usually the case the reason for it is to be found in the circumstance that I came in my wanderings through the medical field upon regions where the gold was still lying by the wayside. Fortune is necessary to be able to distinguish gold from the base metals, but that is no great merit."

Let this portrait which shall henceforth grace the walls of our beloved academy, this likeness of a prince of science, a teacher of teachers, one of the greatest physicians of his time, remind present and future academicians of Koch's motto in life: "Nunquam otiosus" (Be never idle). Let it be to us an inspiration, an incentive, and a reminder of the fact that, though much has been done, there is still more to do.

ON PLYOROSPASM.*

By MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

Pylorospasm or spasmodic contraction of the pylorus can exist for a short period of time and disappear, or it can make its appearance quite frequently and last a long while. Rarely pylorospasm exists without any apparent cause (idiopathic form). More frequently, however, this condition is secondary and due to organic affections in the neighborhood of the pylorus (ulcers of stomach or duodenum, gallstones, etc.). In this paper I intend to deal principally with the chronic form of pylorospasm.

This is a frequent affection, which in its first stages is often overlooked. The principal symptoms are pains in the epigastric region, sometimes radiating more to the right side of the abdomen. Vomiting may exist. In the severe forms of pylorospasm peristaltic restlessness is encountered and the pylorus may occasionally be palpated and felt as a smooth oval tumor. If ischochymia is fully developed the suffering is great and the picture of the disease resembles that found in an organic stricture of the pylorus. Such an instance of a spastic contraction of the pylorus, simulating an absolute benign narrowing of the pylorus, I herewith sketch very briefly.

Fig. 1.—Pyloric portion of stomach and part of the duodenum of Dr. B. F. B., who died in the German Hospital, New York, on December 6, 1908. The pylorus is perfectly patent; near it within the stomach is a small round ulcer.

B, about sixty-two years old, had been troubled with recurrent attacks of gastralgia and vomiting for the last five years. Hematemesis three years ago. For the last five months patient was never free from distress; he vomited almost every day large quantities of highly acid chyme. The stomach extended to hand's width below the level. There was peristaltic restlessness of the stomach in a marked degree, and the organ in its fasting state contained food from the previous day. The symptoms becoming steadily more aggravated and patient losing in strength and flesh, an operation of gastroenterostomy was performed. Patient lived one week and died from symptoms of inanition (persistent vomiting then coma). At autopsy the pylorus was found not stenosed, but there existed an ulcer nearby leading to absolute pylorospasm. (See Fig. 1.)

The differential diagnosis between pylorospasm

*Read before the Medical Society of the District of Columbia on November 23, 1910, at Washington, D. C.

and an organic stricture of the pylorus is not easy. The rice test (a rice meal given in the evening and followed by gastric lavage in the fasting condition the following morning) will always show the presence of almost the entire quantity of rice in the stomach in a case of fully developed organic stenosis of the pylorus. In pylorospasm, however, the rice test will show different results at different times, sometimes the entire quantity being found, while at others only a small amount is recovered or nothing at all. The duodenal bucket will never reach the duodemum in a real narrowing of the pylorus, while in pylorospasm as a rule it will do so. The easiest way to recognize whether the bucket has passed the pylorus is to ascertain whether the lower part of the thread next to the bucket is golden yellow or greenish yellow, due to the presence of bile. This, if present, is a positive sign of the bucket having passed the pylorus, provided the bile stain on the thread extends only for a short distance (10-15 cm.). If one-third or almost half of the thread (being 75 cm. long) is bile stained, this would indicate a regurgitation of bile into the stomach and would therefore not permit any conclusions regarding the passage through the pylorus.

The treatment of pylorospasm must first be directed to a view of eliminating or curing the primary affection; rest cure or duodenal feeding for ulcer of the stomach or duodenum, removal of gallstones, etc. Such treatment, if carefully carried out, very often results in the disappearance of the pylorospasm. Thus in two patients, in whom the pylorus could be distinctly felt as a small tumor of the size of a walnut accompanied by slight ischochymia and distinct signs of ulceration—in one of them in the stomach (Wm. L. B.[1]), and in the other in the duodenum (McC.[2])—after a period of duodenal alimentation of two weeks' duration the tumor has disappeared and likewise the ischochymia.

In those cases in which the pylorospasm is idiopathic, or when the primary lesion cannot be entirely eliminated, stretching of the pylorus is of value. This mode of treatment corresponds to the same procedure practised in chronic cardiospasm, particularly when combined with dilatation of the esophagus. In fact the brilliant results obtained in the latter condition led me to attempt this treatment for pylorospasm.

Two kinds of instruments may be used for the stretching of the pylorus, one being a dilating, inflatable catheter for the pylorus which I[3] described last year. This instrument is introduced over the thread of duodenal bucket, which must be given the night previous. Recently I have used a simpler instrument constructed on the principle of the duodenal pump, which may be introduced directly (see Fig. 2).

The new pyloric dilator (see Fig. 2) consists of a small metal endpiece to which is attached a thin rubber tube (8 mm. circumference and 1 m. long), bearing markings I = 40 cm.; II = 56 cm.; III = 70 cm. and 80 cm. Right next to the metal piece and fastened to it and the tube is a tiny rubber balloon covered with silk gauze. The tube is provided with a few holes within the balloon and is connected at its distal end with a stopcock and a graduated glass syringe. The latter serves the purpose of injecting a certain amount of air into the balloon and thus inflating it.

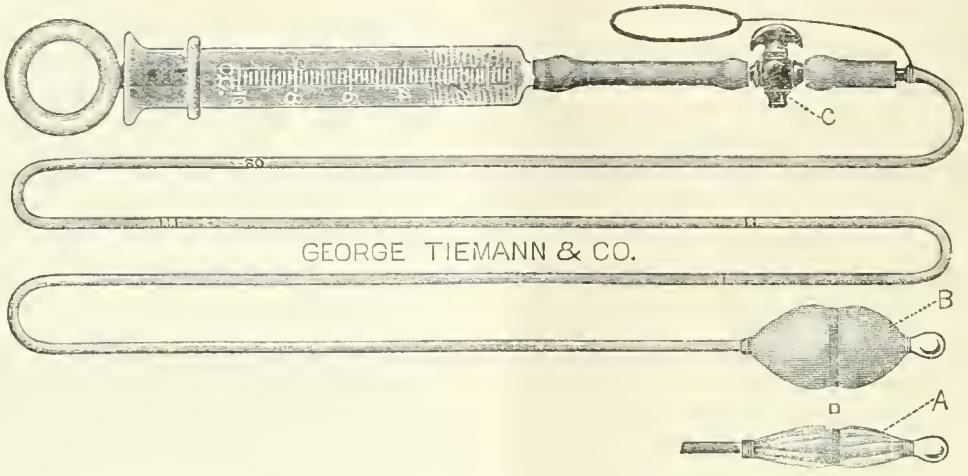


Fig. 2.—The Pylorodilator: A. Balloon with silk gauze covering in collapsed condition. B. The same inflated with air. C. Stopcock. D. Small rubber band to prevent bulging out of the gauze bag.

In the first two cases of stretching of pylorus I used the dilating inflatable pyloric catheter and one of them was fully described in the *Illinois Medical Journal*.[4] All my other patients were treated with the new pyloric dilator.

Method. The pyloric dilator is introduced in the same manner as the duodenal pump. After emptying the rubber balloon of its air contents (this is done by drawing the piston of the syringe outward), the cock is closed. The endpiece of the dilator is now dipped in lukewarm water and introduced in the pharynx of the patient. The latter drinks some water and the instrument moves into the stomach. It is now left in the digestive tract for several hours, or, best, inserted before the patient retires, and left there over night. For in pylorospasm it sometimes takes a long time for the apparatus to pass into the duodenum. In the morning the stretching is performed. Before doing this it is necessary to ascer-

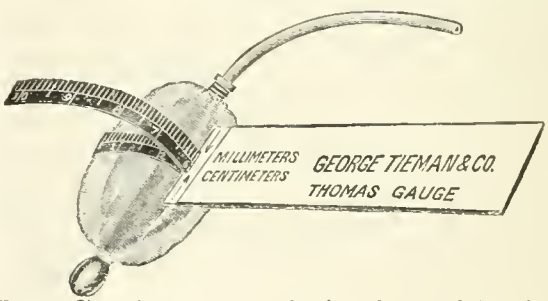

Fig. 3.—Shows how to measure the circumference of the pylorodilator with Thomas' gauge.

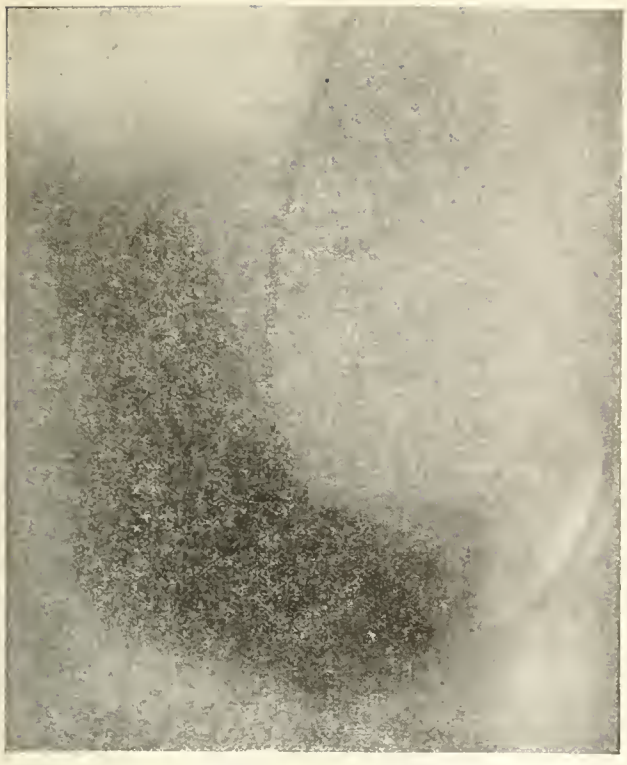

FIG. 4.—A. X-ray photograph of patient, E. F., lying with abdomen on the plate with pyloric dilator in the digestive tract and a bismuth-buttermilk mixture in the stomach. The end of the pyloric dilator is distinctly visible in the descending portion of the duodenum; right above it is the balloon filled with air, which appears as a bright oval area. The stomach is outlined as a dark area.

tain whether the dilator is in the duodenum. This is done by estimating the length of tubing within the digestive tract (it should be in to mark III or 70 cm.), and by drawing the tube slightly outward. If a slight resistance is felt the probability is that ance is encountered and the marking on the tube the apparatus is within the duodenum. In the stomach the apparatus may be moved without resistance. If no resistance is encountered the balloon is inflated and the pulling now again tried Lack of resistance is then a positive sign that the instrument is in the stomach. In this case the balloon must be deflated and left in the digestive tract still longer. If after inflation of the balloon a distinct resistance is felt, then the instrument is pulled slowly forward until the pylorus is reached. Here a strong resistance generally shows mark II within the mouth. If the tube is now drawn forward there is a sensation as if the end of the instrument is held tight by something that drags along with it, not being able to escape it. It is not permissible to use much force. The balloon is then made somewhat smaller by pulling the piston of the syringe and thus deflating it slightly. This is repeatedly done until the end of the dilator by a slight pull passes through the pylorus. Using a graduated syringe one notes the amount of air in cubic centimeters existing in the balloon during its passage through the pylorus. Within the stomach there is no resistance felt when drawing the dilator until the cardia is reached. Here the dilator should be entirely deflated and withdrawn, which is accomplished without trouble. Should, however, a resistance be encountered at the introitus œsophagi, the patient should swallow and while his larynx moves upward the instrument is gently removed without applying any force.

Wash the instrument, dry it off with a towel—now fill it with the same amount of air contained in the balloon when passing the pylorus and measure the circumference, best with Thomas's adaptable gauge (Fig. 3).

The following radiograms (4, 5, 6)* of patient E. F. illustrate the position of the dilator during the entire procedure: A. Endpiece with balloon in the descending portion of the duodenum; B. the balloon just in front of the pylorus pushing the latter toward the left; C. balloon after its passage through the pylorus, lying in the cardiac portion of the stomach. The stretching may be repeated once a week.

The results obtained were uniformly good. I herewith attach a short table of the cases treated with the new dilator:

TABLE OF CASES OF SPASTIC STENOSIS OF THE PYLORUS TREATED WITH THE NEW PYLORIC DILATOR

No.	Name	Prominent Symptoms	How Many Times Stretched	Width of Pylorus Expressed in Mm Circumference	Remarks
1	Mrs. A. E. B.	Gastralgia tarda; dilated stomach; euchlorhydria.	6	52	
2	E. F.	Dilatation and ulcer of stomach, moderate ischochymia.	5	54	
3	J. M.	Dilated stomach, pains, vomiting, slight ischochymia.	1	50	
4	Mrs. F. R.	Dilated stomach; vomiting; ischochymia.....	2	56	
5	G. B. T.	Dilatation and peristaltic unrest of stomach; ischochymia.	3	60	Pylorus could first be felt as oval tumor which later disappeared.
6	H. T.	Gastralgia periodica. Hypersecretion with slight ischochymia.	1	52	Was on duodenal alimentation before stretching.
7	Miss E. S.	Ulcer of stomach; severe gastralgia.. ..	2	40	Real stenosis complicating the pylorospasm.
8	Mrs. C. H. G.	Dilated stomach; vomiting; emaciation.	1	50	
9	Mrs. C. B. C.	Marked ischochymia Peristaltic restlessness of stomach.....	2	63	

I will describe two of these cases more fully.

CASE I.—March 31, 1910. Mrs. F. R., forty-six years old, was always well until three months ago when she began to be troubled with nausea, vomiting, constipation, headache, pain in upper abdomen, insomnia, and anorexia. She lost considerably in flesh. Her physician sent her to the hospital with a probable diagnosis of cancer of the stomach. Status præsens: Patient is a somewhat emaciated elderly woman; there are no eruptions

*I am indebted to Dr. L. G. Cole for these beautifully executed radiograms.

or glandular enlargements. Pupils are equal and react to lights. Her tongue is coated; her lungs, heart, and pulse are normal. The abdomen is soft, tympanitic and tender in the epigastrium. The stomach is considerably dilated, extending to about

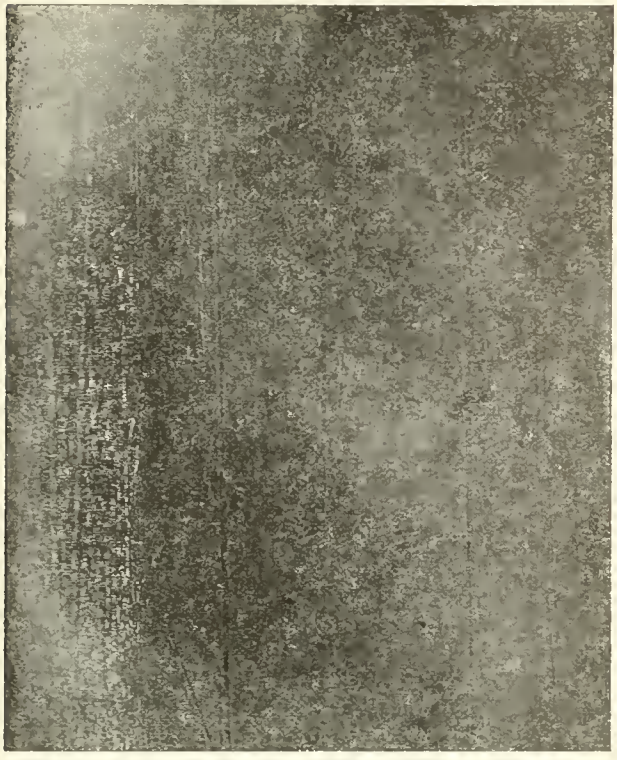

FIG. 5.—B. Same as Fig. 4, a few minutes later, after pulling the dilator up, in front of the pylorus. The dilator with the inflated balloon are seen outside of the stomach, in the duodenum, invaginating the pylorus slightly into the stomach.

three fingers below the navel. Washing of the stomach in the fasting state shows the presence of food from the previous day. The urine is negative. The blood is normal, the stomach contents show free HCl 36, total acidity 60, also the presence of food remnants from the day before, no lactic acid and no blood. Treatment by gastric lavage is ordered every other day—the pylorus is stretched by means of the dilator on April 9 and April 16. After stretching the pylorus the stomach began to be empty in the fasting condition. Patient could eat a variety of food without distress and gradually recovered.

CASE II.—November 6, 1910. George B. T., aged sixty-seven, began to suffer fifteen years ago from indigestion and gave up smoking and drinking on that account. Five years later patient consulted me for his affection.. At this time his main trouble was pain in the stomach about two hours after eating. Since this time he has been treated for his stomach trouble at different times. At present his main complaint is a feeling of great pain in his stomach and gas pains immediately after eating. He has to belch a great deal and has constantly a sour, bitter taste in his mouth. The pains are of a severe type and patient cannot sleep. Every few days he vomits a large quantity. He then feels very much relieved. At no time has he to his knowledge vomited blood. During the last illness he lost twenty-four pounds in weight. His stools are slightly costive and have never contained mucus or blood. At one time he had considerable mucus in his vomitus but no more. Present condition: The stomach is greatly dilated, extending to the pubis. The pylorus can be indistinctly felt as an oval tumor of walnut size. There are distinct peristaltic waves visible, moving from left to right, covering the left side of the abdomen. The stomach is examined in the fasting condition: 700 c.c. of a watery fluid mixed with food are obtained; HCl + Acidity = 96. Occult blood is present. Patient is kept abed on a strictly liquid diet and on the magnesia and bismuth medication. The vomiting continues, also the severe pain. Patient is at times so weak that he can hardly talk. Washing of the stomach is performed every day. The amount of residue fluctuates between 300-700 cc. and patient is wretched. The duodenal bucket is introduced at night and is withdrawn the following morning in the fasting condition. It returned filled with bile and the lower end of the thread attached to the bucket was golden yellow for 12 cm. This showed that the pylorus was permeable.

The pyloric dilator was then inserted at 6 P. M. and left in the digestive tract until the following morning. The pylorus was then stretched on November 2, 1910. Patient stopped vomiting and could eat better without distress. On November 3 the stomach contained 90 c.c. of fluid mixed with some food. On the following days, however, it was empty. Patient began to partake of solid food. About ten days later there was a relapse and patient began to vomit and felt distressed. The peristaltic restlessness of the stomach likewise returned. The pyloric dilator was again applied and immediate improvement followed, the stomach emptying normally and patient being able to enjoy eating. He has lately gained ten pounds in weight. In the latter case the stretching of the pylorus was almost a life saving procedure. For the patient was in no

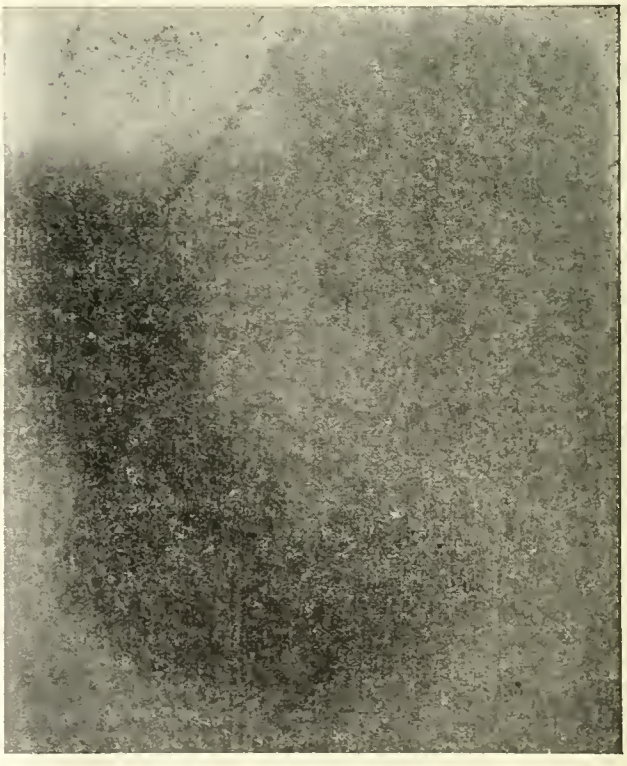

FIG. 6.—C. Same as Fig. 5, a few minutes still later, after having pulled the dilator through the pylorus into the stomach. The end of the dilator can be seen in the cardiac portion of the stomach.

fit condition to be operated and would apparently have succumbed had his pylorus not been stretched. This procedure acted like magic. The vomiting ceased; the stomach emptied itself over night and all distress disappeared.

The statement of Delangre and Monprofit appears to be upset by the pyloric dilator. Delangre[5] expresses himself as follows: "Monprofit also has said that the real practical indication for gastroenterostomy is found in benign stenosis of the pylorus, an indication which will always stand because, even if a cancer sernm should be found, it is unlikely that a means of treating this form of stenosis should be discovered."

As shown in this paper, the spastic form of pyloric obstruction can be cured without surgical intervention. It appears to me that benign organic strictures of the pylorus which have not as yet progressed too far will also be accessible to the above method of treatment. I shall endeavor to investigate this subject more fully and publish the results later on.

SOME REMARKS ON THE SURGICAL DISEASES OF THE BILIARY PASSAGES.*

BY ALEXANDER BRYAN JOHNSON, M.D.,

NEW YORK.

NO NEW facts are contained in this paper, nor is the practical application of any new theory set forth. It is my purpose to call your attention to some of the phenomena of gallstone disease, well known to surgeons of experience, but in my belief not clearly recognized in their practical bearings by many purely medical practitioners.

Writing several years ago I stated the common belief in regard to the frequency of gallstones as follows: "It is estimated that gallstones are found at autopsy in about one body in ten; in all but five per cent. of the cases no symptoms are produced or symptoms so slight in character that the individual has never had his attention directed to his biliary apparatus." More recently careful study of the histories of patients coming to autopsy from various diseases has shown that, whereas gallstones are probably less frequent than just stated, yet when they do exist they cause symptoms in a very large proportion of cases. Such symptoms may not have been severe; jaundice may never have occurred. In many a diagnosis of gastric dyspepsia of one sort or another has been made, and yet the presence of gallstones and of associated lesions at autopsy has perfectly accounted for the symptoms present during life.

One of the commonest errors in diagnosis in my experience has been to exclude gallstones because there has been no history of jaundice.

Those familiar with the actual conditions as seen at operation are well aware that so long as gallstones remain in the gall bladder they bear no necessary relation to jaundice. Another group of facts perhaps less generally known, or at least not practically applied, is that owing to the poor lymphatic supply of the gall-bladder, as pointed out by W. J. Mayo, severe purulent infection of the gall-bladder may occur with but trifling constitutional disturbance. There may be no fever, no notable increase of leucocytes, no jaundice. The symptoms and signs may be merely epigastric pain and tenderness over the gall-bladder, with or without a palpable tumor. The following case well illustrated the relatively mild symptoms present, though the lesions found were severe:

"The following case history illustrates that gallstones situated in the gall-bladder may give rise to trifling constitutional disturbance, even though they may have caused pressure ulceration and a purulent inflammation of the gall-bladder, threatening immediate perforation with all the dire consequences. The case is one upon which I operated in January, 1909. A woman, forty years of age, was admitted to the New York Hospital with the following history: During the past three years she had suffered from time to time with attacks of epigastric pain, which had been diagnosticated by her physician as acute gastric dyspepsia. Twenty-four hours before her admission to the hospital she was suddenly seized with severe pain, referred to the right upper quadrant of the abdomen, and came to the hospital. Upon admission she complained of very intense pain in this region. She had not vomited. There were no notable constitutional symptoms. Her temperature was normal, her pulse was only slightly accelerated; the blood count showed no notable increase of leucocytes, nor were the polynuclear cells relatively increased in number. She was not jaundiced. Palpation of the abdomen showed nothing abnormal except moderate tenderness over the region of the gall-bladder. The patient was kept under observation for twenty-four hours. No new symptoms developed, but the pain in the region of the gall-bladder continued severe. At the end of thirty-six hours the gall-bladder was removed. It contained two large stones, one of them impacted in the neck of the gall-bladder, where it had produced pressure ulceration of the mucosa and muscular coat. The necrosis had extended almost to the peritoneal coat, and perforation would probably have occurred within a day or two. The gall-bladder contained mucopus. Normal convalescence.

Within a week of the time when I operated upon this case I saw and operated upon another in whom the symptoms were almost identical with the first, but where distended gall-bladder was distinctly palpable below the free border of the ribs. Although the gall bladder of this patient was filled with stones the patient stated she had never had a severe attack of pain in the abdomen, nor had she ever been jaundiced. In this case there was purulent cholecystitis. The cystic duct at its junction with the gall-bladder was the seat of a narrow stricture. A small stone was impacted just distal to the point of narrowing. The gall-bladder was removed. Normal convalescence.

Although an early diagnosis of gallstones is possible in all but a small percentage of cases, I think my surgical colleagues will bear me out when I say that in the hospitals of New York City we receive our cases of gallstone disease from the physicians who send them only after months or years of medical treatment without benefit. The lesions are severe, prolonged jaundice, suppurative cholecystitis, perforation of the gall-bladder followed by purulent peritonitis or abscess, dense perigastric adhesions, causing obstruction of the pylorus and dilated

*Read at a meeting of the Medical Society of the County of New York, November 28, 1910.

stomach, or sometimes even obstruction of the common bile-duct, contracted, shrunken and functionless gall-bladders, severe general sepsis, cholangitis, chronic pancreatitis with obstruction to the escape of bile and pancreatic secretion into the intestine, these are some of the conditions commonly found at operation or autopsy.

The experience of surgeons throughout the world is that in cases of gallstone disease operated upon early the mortality is trifling and restoration to health the rule.

In the presence of advanced lesions on the other hand, the technical difficulties of the operation itself are much greater and require a higher degree of surgical skill and judgment for their proper performance. The operative procedures are necessarily more severe and prolonged, the patients are in worse condition to endure them and the mortality is much higher. As every surgeon knows, prolonged severe jaundice in itself adds greatly to the risk of operation and increases the dangers of shock and hemorrhage, but not only are the immediate dangers of operation greater but also the chances of operative cure are diminished.

In some cases the gall-bladder will be found necrotic, or perforated, or in such condition of purulent infection that it must be removed; in others the cystic duct may be found obliterated and the gall-bladder either distended or shrunken, containing in either case stones; these cases also demand the removal of the gall-bladder.

Now it is by no means a matter of indifference whether or not we remove the gall-bladder. A few years ago the operation of cholecystectomy was very popular among American surgeons, and, though not hopelessly diseased, the gall-bladder was often removed as offering the patient the best guarantee of cure; more extended experience has, however, shown that under certain conditions the possession of a gall-bladder may be a very valuable asset.

Many cases of common duct stone are associated with infection not only of the biliary passages, but also of the pancreas, and chronic pancreatitis may cause biliary obstruction of a serious and obstinate character. Experience shows that diversion of the stream of bile through the opened gall-bladder to the surface of the body for days or weeks causes the pancreatitis and consequent biliary obstruction to subside in a large proportion of cases, after which the biliary fistula may be permitted to close, or may be closed. If the gall-bladder be *removed* the drainage of bile to the surface is more *difficult* and *uncertain*, moreover cicatricial contraction or renewed infection may cause a recurrence of biliary obstruction and jaundice, or in other cases a persistent biliary fistula may remain. In the presence of these conditions the surgeon finds himself confronted by a formidable problem; if he succeeds in solving it he will consider himself fortunate.

If a gall-bladder be preserved, patent to the hepatic duct, an anastomosis may still be made between the gall-bladder and intestine and the stream of bile thus returned to its proper course. There will be a certain number of cases in which cholecystenterostomy will be selected as a primary measure, but it is not to them that I refer.

The judgment of individual surgeons will cause them to select slightly different operations, in similar cases, but what I wish to emphasize is that if cases of gallstone disease be operated upon early, before serious changes have occurred in the biliary passages and surrounding viscera, the operations will be easy, simple, and almost devoid of risk. The chances of cure are excellent.

If, on the other hand, these cases are allowed to drag along for months and years with recurring attacks of pain and jaundice the patients will be in poor condition to withstand shock, the operative procedures will be necessarily more severe, the mortality much higher, and the chances of permanent cure much diminished.

12 East Fifty-eighth Street.

OLIVER WENDELL HOLMES; HIS WORK IN ESTABLISHING THE CONTAGIOUS NATURE OF CHILD-BED FEVER.*

By T. W. HARVEY, M.D.,

ORANGE, N. J.

The year 1809 had to wait one hundred years before it really came into its own, when the centennial came around and it was noticed how many great leaders of men had been born in that year. Among them all, with the exception of Darwin, no one is so interesting to medical men as Oliver Wendell Holmes, not because of his lilting verse, nor his fascinating prose, nor his cheerful philosophy, but because of his work as a medical man. His long service as a teacher of anatomy, his strenuous attacks upon charlatanism and chicanery, his efficient and illuminating efforts in establishing the contagious nature of puerperal fever, and the example that he gave of a highly trained medical man who at the same time could be a cultivated and polished man of the world, render him an object for the admiration and veneration of his professional brethren.

Few medical men have been successful, both in general and in medical literature, but Dr. Holmes presented just such a combination. His popularity as a writer of verse and of the most delightful prose, overflowing, as it is, with whimsical conceits and a quaint philosophy that thinly veils a sharp and trenchant sarcasm aimed at the many shams and pretenses of society, has far overshadowed the work that he did as a medical man. We forget the long and arduous medical training, the thirty-five years as professor of anatomy, and the excellence of his medical essays. We also forget the effect upon his literary work of his medical training.

A sentence of his own will illustrate one phase of my meaning. He says "The humanizing effect of medical studies is seen in the careers and writings of literary men. Goldsmith and Smollett both having studied and practised medicine, could not by any possibility have outraged the natural feelings of delicacy and decency as Swift and Zola have outraged them."

There is something about the study and knowledge of medicine that produces in human minds a stimulus towards quackery, or an intense aversion to it. It also develops an intense and unreasoning loyalty to authority so that as some have expressed themselves, "they would rather be wrong with Hippocrates than right with Paracelsus," or it creates an independence of mind and an intolerance of authority that often goes to the other extreme and simply takes the other path from pure obstinacy.

Dr. Holmes certainly had the hatred of quackery —quackery in any department of learning; but he also had no blind devotion to authority. In fact,

*Read before the Orange Mountain Medical Society, May 20, 1910.

early in his career he thus defines his position: "I learned in Paris not to take authority when I have facts, not to guess when I can know, not to think a man must take physic because he is sick."

His writings abound with similes and illustrations drawn from medical lore. "His medical training peeps out in every paragraph." (Conan Doyle.) So the effect of his training is seen in his portraits of medical men; nowhere do we find the monstrosities of Dickens, Hogarth and Molière, but always he draws them sympathetically, although keenly alive to their foibles, and delighting to puncture their hot-air balloons of conceit and deceit; an enemy as he ever is to charlatans he is at all times ready to do honor to the modesty, and charity, and unselfishness of the honest doctor. And while we read in one of his descriptions of the doctor:

"Age lends the graces that are sure to please;
Folks want their doctors mouldy like their cheese."

In another place we read:

"How blest is he who knows no meaner strife
Than Art's long battle with the foes of life;
No doubts assail him, doing still his best
And trusting kindly Nature for the rest."

Again:

"Thoughtful in youth, but not austere in age;
Calm, but not cold, and cheerful though a sage;
Too true to flatter and too good to sneer,
And only just when seemingly severe;
So gently blending courtesy and art
That wisdom's lips seem borrowing friendship's heart.
Taught by the sorrows that his age had known
In others' trials to forget his own,
As hour by hour his lengthened day declined,
A sweeter radiance lingered o'er his mind.
Cold were the lips that spoke his early praise,
And hushed the voices of his morning days,
Yet the same accents dwelt on every tongue,
And love renewing kept him ever young."

Born of good old New England stock, he spent his youth among books and in the intellectual atmosphere peculiar to a New England clergyman's home, where the everyday table talk was sure to be on a high plane, where one was more likely to hear discussed the principles of philosophy than the news of the divorce court.

There are still a few homes in that old country where one will find that the chosen topics for conversation are entirely worth while, and are not the froth and fume of sensational and mendacious news gathering; but in the early days of the last century high thinking and hard work went hand in hand with the frugal living. The genial "Autocrat of the Breakfast Table" simply exemplified and glorified the customs and habits of his good forefathers, among whom all kinds of subjects were considered worthy of the most careful and analytical study in the family circle as part of the education and training of its younger members, who were expected to keep their ears open and their mouths shut.

Dr. Holmes' appreciation of these good old Puritan progenitors appears in the following lines to the first one, the emigrant:

"But who the youth his glistening axe that swings
To smite the pine that shows a hundred rings?
His features?—something in his look I find
That calls the semblance of my race to mind.
His name?—my own; and that which goes before
The same that once the loved disciple bore.
Young, brave, discreet, the father of a line
Whose voiceless lives have found a voice in mine;
Thinned by unnumbered currents though they be,
Thanks for the ruddy drops I claim from thee!"

In one of his letters appears another reference to his youth which is so characteristic of his humor that I cannot omit to quote it. To some one telling him that he was brought up on the bottle he writes that this knowledge "has made me feel as tenderly every time I visit my wine cellar as Romulus and Remus did when Faustula carried them to the menagerie and showed them the wolf in the cage."

After graduating from Harvard he vacillated for a year between law and literature, and at the end of that time began his medical training at the Harvard Medical School, finishing his studies in Paris.

It seems as if it must have been the golden age of French medicine, and to Dr. Holmes' quick receptive mind there did not seem to be time enough in each day to make the most of his opportunity. In a letter to his parents he says, "If I had my own way I would never return until I could go home with the confidence of placing myself at once at the head of the younger part of the profession." In another letter he describes the manner of his training in operative technique. One is compelled to compare the ease of obtaining material in Paris with the difficulty that existed in Great Britain and in the United States at the same period. It is not difficult to find one of the reasons for the superiority of French medicine in the early part of the nineteenth century. In this letter he says:

"Among other things I have turned my attention to operating, and in the course of a few weeks I have become an expert and rapid operator. To give you an idea of how this is possible I will tell you how I have occupied my time during this time. On the site of the ancient cemetery of Clarmart, about a mile from my room, there now stands another receptacle for the defunct, where they are consigned to the open hand of science. This establishment is not one of the little, infernal, suffocating holes in which the unhappy native of our uncivilized land is often obliged to pursue his labors, but a spacious courtyard, with several neat, white halls, and a garden and fountain in the middle. In these precincts hundreds of students dissect during a part of the year and operate during another. After having taken our lessons in operative surgery, a Swiss friend of mine—whose intimacy has been enjoyed successively by poor Jackson, by Bowditch and now by myself—the Swiss student and myself, I say, bought a few instruments together and began to make ourselves operators. It is an odd thing for anybody but a medical student to think of, that human flesh should be sold like beef or mutton. But at 12 o'clock every day, the hour of distribution of subjects, you might have seen M. Bizot and myself—like the old gentleman one sometimes sees at a market—choosing our day's provision with the same epicurean nicety. We paid fifty sous apiece for our subject, and before evening we had cut him into inch pieces. Now all this can hardly be done anywhere in the world but at Paris. In England and America we can dissect, but rarely operate upon the subject, while here one who knows how to use his hands, and who gives his attention exclusively to the subject for a time, may, as I have said I have done, become an expert operator in a few weeks. I have told you all this to let you know that I am not staying at Paris for nothing."

After a short tour of the continent he returned to Boston in 1836 and immediately commenced to practise medicine. According to his biographers he never became a great practitioner, but early took up with the literary side of his profession, as he won the Boylston prize for medical essays in 1836 and 1837, the title of his essay of 1836 being "Intermittent Fevers in New England." He was made professor of anatomy at Dartmouth Medical School in 1838, and was appointed to the chair of anatomy and physiology at Harvard in 1847, and delivered the lectures on anatomy at that college for thirty-five years, resigning in 1882.

One of his students refers to the many bright sayings and references that he used to illustrate the dry details of his subject. He was very proud of his anatomical plates of the old anatomists, of which he was an ardent collector, "in which," he says, "lively ladies display their viscera with a coquettish grace, implying that it is rather a pleasure than otherwise to show the lace-like omentum and hold up their appendices epiploica as if they were saying 'These are our jewels.'" (Otis.)

Before he was appointed professor of anatomy in 1843 he had written and published his essay on the "Contagiousness of Puerperal Fever." The first knowledge that we have of the recognition of puerperal fever as a distinct disease is in the description of an epidemic that occurred at the Hotel Dieu at Paris, in 1664. The earliest theories were based on the idea of the retention of the lochia and the decomposition of remnants of placenta, and this explanation of the morbidity of child-bed goes back to Hippocrates and was believed in by Galen.

Here and there through the ages a light had burned true for a short time, and in the writings of Thomas Denman, a great English obstetrician of the eighteenth century, we read, "There is another consequence of an epidemic or even a sporadic puerperal fever, in which it would be criminal to be silent. This is the contagious nature of these fevers, it having been suspected and being now fully proved that they may be and often have been conveyed by midwives or nurses from one patient to another. This fact explains the reason why persons practising for many years with the most enviable success have at one or more periods of their lives, without any change in the principles or practices of their practice, met with a number of unfortunate cases, when perhaps an adjoining neighborhood has been entirely free from such disease."

Dr. John W. Francis, of New York City (1821), editor of the American edition of Denman, says, "The contagiousness of puerperal fever has been denied by some writers, while others have represented it to be so to an eminent degree. The records of the Lying-in Hospital of Great Britain confirm this latter opinion." He means those cases in the Royal Infirmary in Edinburgh, reported by Dr. Duncan, Jr., 1816, where the contagion was satisfactorily traced to the nurses. American authorities on obstetrical subjects at this time, however, had not accepted this view and were not at all willing to acknowledge its truth, and when Dr. Holmes' paper appeared attacked it vehemently.

Even with all this teaching of the theory that the disease could be conveyed from one patient to another by the attendant, the application in actual practice of the proper methods to prevent such conveyance was not adopted by the mass of the profession for many years, so that as late as twenty years ago many were willing to say that while such precautions might be needed in lying-in hospitals, they did not consider them necessary in private practice, and I do not believe that full aseptic midwifery has been generally used in private practice more than twelve years.

At that time most of the French writers on obstetrical subjects taught the contagious nature of the disease; opinions that were voiced in the writings of Trousseau in 1850, in which he taught that "the disease had its origin in lesions of the genital tract which were complicated by general secondary lesions the outcome of puerperal infection."

Holmes was probably not aware of the work that Semmelweis was doing at the same time, another illustration of that noteworthy fact that many identical epoch-making ideas will appear at the same time in the minds of different men, as if plural births were the rule in the family of old Father Time. We may be sure, at any rate, that at no time has it happened that a great medical truth has ever ben presented to the world in a more attractive or convincing manner. It is here that his literary genius shows.

The paper was first published in 1843, and with it he presented this proposition: "The disease known as puerperal fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses."

This essay was immediately attacked with much vigor by the great obstetrical authorities of Philadelphia, in which they ridiculed the theories, and questioned the facts of the youthful Boston writer. More and more convinced of the truth of his proposition, in 1855 he republished the essay with his defence, and a most masterful defence it proved to be—a masterpiece of logical arguments and a very high-class literary product.

In the introduction to his paper published at the time when it was reprinted in 1855, Dr. Holmes says, "It happened some years ago that a discussion arose in a medical society, of which I was a member, involving the subject of a certain supposed cause of disease about which something was known, a good deal suspected, and not a little feared. The discussion was suggested by a case reported at a preceding meeting of a physician who made an examination of the body of a patient who had died with puerperal fever, and who himself died in less than a week, apparently in consequence of a wound received at the examination, having attended several women in confinement in the meantime, all of whom, it is alleged, were attacked with puerperal fever." Now it happens that I became acquainted with the widow of this unfortunate physician, Dr. Barker, and that she told me that all these women died.

Dr. Holmes, in the beginning of his paper, marshals a long array of facts supporting his theory, quoting widely from English writers, and narrating numerous instances that had come under his own observation and within the knowledge of his colleagues. This mass of evidence is arranged in an orderly manner, and most systematic and logical arguments are based thereon from which to deduce his conclusions. Of this evidence he himself speaks as follows:

"In view of these facts it does appear a singular coincidence that one man or woman should have ten, twenty, thirty, or seventy, cases of this rare disease following his or her footsteps with the keenness of a beagle, through the streets and lanes of a crowded city, while the scores that cross the same paths on the same errands know it only by name. It is a

series of similar coincidences which has led us to consider the dagger, the musket, and certain innocent-looking white powders as having some little claim to be regarded as dangerous. It is the practical inattention to similar coincidences which has given rise to the unpleasant but often necessary documents, called indictments, which have sharpened a form of the cephalotome sometimes employed in the case of adults, and adjusted that modification of the fillet which delivers the world of those who happen to be too much in the way while such striking coincidences are taking place."

Again he says: "Having thus narrowed its area to a limited practical platform of discussion, a matter of life and death, and not of phrases or theories, it covers every inch of it with a mass of evidence which I conceive a committee of husbands, who can count coincidences and draw conclusions as well as a Synod of Accoucheurs, would justly consider as affording ample reasons for an unceremonious dismissal of a practitioner (if it is conceivable that such a step could be waited for) after five or six funerals had marked the path of his daily visits, while other practitioners were not thus escorted. To the profession, therefore, I submit the paper in its original form, and leave it to take care of itself."

Taking up the defense of his conclusions he thus answers his antagonists: "I appeal from the disparaging language by which the professor in the Jefferson School of Philadelphia would dispose of my claims to be listened to. I appeal, not to the vote of the Society for Medical Improvement, although this was an unusual evidence of interest in the paper in question, for it was a vote passed among my own townsmen; not to the opinion of any American, for none know better than the professors in the great schools of Philadelphia how cheaply the praise of native contemporary criticism is obtained. I appeal to the recorded opinions of those whom I do not know, and who do not know me, nor care for me, except for the truth that I may have uttered; to Copland, in his 'Medical Dictionary,' who has spoken of my essay in phrases to which the pamphlets of American 'scribblers' are seldom used from European authorities; to Ramsbotham, whose compendious eulogy is all that self-love could ask; to the 'Fifth Annual Report' of the Registrar-General of England, in which the second-hand abstract of my essay figures largely, and not without favorable comment, in an important appended paper. These testimonies, half forgotten until this circumstance recalled them, are dragged into the light, not in a paroxysm of vanity, but to show that there may be food for thought in the small pamphlet which the Philadelphia teacher treats so lightly. They were at least unsought for, and would never have been proclaimed but for the sake of securing the privilege of a decent and unprejudiced hearing."

And finally he thus sums up his own satisfaction in the work that he has accomplished: "I do not know that I shall ever again have so good an opportunity of being useful as was granted me by the raising of the question which produced this essay. For I have abundant evidence that it has made many practitioners more cautious in their relations with puerperal females, and I have no doubt that it will so still, if it has a chance of being read, though it should call out a hundred counterblasts, proving to the satisfaction of their authors that it proved nothing. As for my part, I had rather rescue one mother from being poisoned by her attendant than claim to have saved forty or fifty patients to whom I had carried the disease. Thus I am willing to avail myself of any hint coming from without to offer this paper once more to the press."

Happily he lived to see the opinions which he thus championed become the common belief of all the medical world, and the practice of midwifery and obstetrical nursing so entirely reformed that puerperal fever in epidemic form has been entirely banished from obstetrical practice.

Many minds have contributed to the task of working out the nature of the contagion and the multiform agencies conducive to its spread, and the methods for preventing the pernicious activity of such agencies, but no medical controversialist had before his writing brought to the work a more brilliant rhetoric or more pitiless logic.

Turning again from the work to the man, it is difficult to imagine that a man, a physician, could have had a more delightful existence than did Dr. Holmes. Of course, none of us can enter the inner consciousness of any other man and know of the disappointments, griefs and tragedies that may exist beneath the complacent and smiling exterior, but certainly as it appeared it presents every requisite of a successful and an enviable life.

Born in just that part of the New World where intellectual superiority was most appreciated, at a time when social position was dependent more on brains than on wealth, his medical training completed in Paris, at that time the medical center of the world, with Broussais, Andral, Louis, Velpeau, Lisfranc, and Ricord as professors, a constellation of medical stars whose radiance is still shining through the darkness of an hundred years; early welcomed into that literary circle in his native town which later became the most noted group of wits and intellectuals since the days of good Queen Bess; the idol of his class of '29, for more than fifty years of post graduate life; a professor in his alma mater; living through a period of the world's history full of new discoveries appealing most strongly to a sensitive, poetic imagination; living to see the children of his brain become the delight of his countrymen and his son rise to the highest position in his profession; dying peacefully at the end, like the dropping of the last leaf of his own beautiful poem; one can hardly draw in a few words a more satisfying picture of well-earned success crowning an industrious and a happy life.

463 Main Street.

SENILE DEBILITY.

By I. L. NASCHER, M.D.,

NEW YORK.

Senile debility is the most obvious of the senile manifestations, the most distressing physically and depressing mentally to the individual, yet it has received less attention than any of the senile ailments. Senile debility is not a disease nor a symptom of a disease and it is generally neglected by the physician unless he is called upon to do something for it. In that case he will probably give a placebo, perhaps a tonic, with the remark "old age" as a finality that leaves nothing more to be said or done.

Senile debility is a mental and physical discomfiture which cannot be prevented, but the distress can sometimes be relieved, the mental attitude improved, and a semblance of old-time vigor and virility restored.

In its widest sense the term is applied to a general weakness of the organism in old age, the organs

perform their functions less energetically, voluntary muscles do not respond to the will as rapidly nor as actively, physical power is weakened, coordination is lessened, and the mind, including the will, sensations, and intellect, is impaired. In its narrowest sense the term is applied to a loss of strength in the limbs. It is hardly necessary to describe the features of senile debility. The bent frame, the tottering limbs, the trembling hands, the coarse tremor of the head, the attitude, the gait, are all too well known to require description.

The direct causes of senile debility are the waste of muscle, the senile changes in bone, cartilage, ligament and tendon, and lessened innervation. There is also generally a psychic factor involved, either causative or resultant, which exaggerates the manifestations of senile debility. This psychic factor, which will be discussed presently, may have such a marked influence upon the individual that pronounced manifestations of senile debility may appear with slight physical or anatomical changes. It is not unusual to find decrepit old persons regain vigor and lose the appearance of decrepitude after their admission to a home for the aged. We have then a true senile debility in which the manifestations are due mainly to the physical changes occurring in senility, and a pseudo or psychic form in which the characteristics of senile debility are due mainly to the mental attitude. Let us consider the bent posture of the aged. In true senile debility this is due to anatomical changes; there is waste and weakness of the muscles and ligaments of the back and uneven compression and waste of the intervertebral discs. These discs gradually lose their elasticity, the weight of the body compresses them, the compression being greatest where the discs are thinnest, anteriorly in the dorsal and posteriorly in the cervical and lumbar regions. The anterior margins of adjoining dorsal vertebræ are thereby brought more closely together, spreading the posterior margins, thus producing the exaggerated dorsal curvature. The reverse is going on in the cervical and lumbar regions; not so marked, however, as the cervical discs are subject to less pressure and the lumbar discs are much thicker and more even than the dorsal discs. In addition to the exaggerated spinal curvature the wasted and weakened muscles of the back and neck allow the body to sink and the head to fall forward into the characteristic attitude of senile debility. As these changes proceed very slowly the senile stoop arising therefrom ought not appear until in advanced old age. In the psychic form of senile debility the senile stoop may appear early for this reason: The most natural position of an individual is the one involving the least physical effort, hence one allowing complete relaxation of the muscles. This is seen in the infant, in sleep, under depressing emotion, and in the careless individual. The erect position, head up, shoulders back, chest out, is the result of effort which, when long continued, becomes a habit. The child is taught to sit up straight and to stand straight because an erect carriage is more pleasing to the eye and is supposed to be more conducive to health. There is, however, always the tendency to relapse into the slouching position, this tendency being overcome, consciously or unconsciously, by a sense of pride in one's appearance. Another incentive to maintain the erect position is the ambition to gain approval in any field of human activity, such recognition being more readily secured when the individual presents a pleasing appearance. The inherent tendency to avoid physical effort is overcome by ambition, pride in appearance, and habit. The last factor is not in itself strong enough to overcome the tendency to slouch. The pride in one's appearance, though arising from self-esteem, is fostered by ambition, the desire to gain approval, and to appear pleasing to others. When ambition is lost this sense of pride goes with it, the person makes no effort to overcome the tendency to slouch, he allows his body to sink, his head to droop, his arms to hang and his legs to drag. This is the usual attitude of the lazy tramp. When the aged individual begins to feel the infirmities that come with advancing years, that he gets out of breath, that he gets palpitation of the heart, that he soon gets tired and that there is a stiffness in his muscles and joints, that make his usual labors more difficult he realizes that his life's work will soon be over. From that moment he loses ambition, he loses interest in his work, in his surroundings, in everything except in his life. He loses the pride in his appearance and makes no effort to maintain the erect bearing of former years. There is now the dread of the inevitable end, perhaps the fear that he has not provided sufficiently for his last years, or that with his death there may be dependents unprovided for, all producing a mental depression which overcomes the habit of erect bearing. The loss of sexual virility may produce the same effect. After ambition and pride in the appearance are lost the individual ages far more rapidly than can be accounted for by the progressive anatomical and physiological changes of senility. That this aging is mainly due to mental influences is evident from the ease with which it may be overcome by mental stimulus. Relieve the old man of worry about means of livelihood in his closing years by placing him in a home for the aged, and he will improve in appearance and in his mental attitude. Flatter an old fellow upon his youthful appearance and activity and you arouse in him a sense of pride in his appearance; he will try to appear youthful by sitting up or standing erect to show that he is not as old in feeling as he is in years. The old soldier, tottering along on Decoration Day, braces up as he passes the reviewing stand and with head erect, shoulders thrown back, chest out, he makes a firmer step, his knees seem more limber, he raises his hand in saluting with a spryness that belies the decrepit appearance of a few minutes before. The same wonderful change is seen in the aged Romeo when he goes a-courting.

When the senile stoop is due to waste of muscle and compression and waste of the intervertebral discs it requires a powerful effort to maintain an erect position even for a few minutes. In some cases where there has been intense physical activity for years the senile changes begin early and there are early manifestations of senile debility. In most cases where these manifestations appear at a comparatively early age, say about sixty, the psychic factor has been the dominant factor in producing them.

Mental stimulation through psychic influences is the natural method of overcoming mental depression. In earlier life ambition, hope and work are the agents opposing mental depression, but in old age ambition and hope disappear and work becomes objectionable. Still it is often possible to arouse ambition and hope and the sense of pride in appearance, and overcome the apparent debility, providing that it is not due to pronounced anatomical changes. In some cases suggestion such as flattery will avail, in some cases hope or the assurance of freedom

from care. No psychic influence will avail when the anatomical changes make the body incapable of responding. I present a few typical cases in which the change in mental attitude produced a change in physical condition. (1) Mr. A. aged 80, was discharged from the shop where he had been employed for many years, on account of his age. He went home, became morose, spoke of the uselessness of living longer, and within a fortnight he presented the appearance of a decrepit old man. His firm was induced to reengage him, giving him lighter work. He became light-hearted and more active than he had been in years. (2) Mr. B. age 71, walked with a cane for years and tottered without it. Remarried and walked into church erect without his cane, and the same evening he danced with his bride and lifted her off the floor. (3) Mr. and Mrs. G., aged 74 and 70 respectively, danced at their golden wedding, and were flattered upon their youthful appearance. For several years they had lived with a daughter, doing no work, believing that they were too old and weak to do anything. Taunted with their activity at the celebration, he resumed his former vocation, locksmith, while the wife resumed her household duties. (4) Mr. N., aged 68, worn out from hard work as a furniture mover, and having no means, being dependent upon the bounty of strangers, presented the appearance of extreme enfeeblement. He was admitted to a home for the aged and within a week he appeared as robust as he had been in earlier years. This marked improvement was due to the release from care about the future. (5) Mr. C., aged 76, was accepted in a home for the aged on account of his almost helpless condition. He was so weak that he could not dress himself and he had to be helped to enter a car. A condition of his acceptance was that he turn over to the home all his property, but before entering he had received a legacy and rather than turn this over he gave up the home and opened a store. For a short time he was quite active in his place, but the business was a failure. The mental depression returned and with it the physical debility.

In these cases the psychic factor played a prominent if not the dominant part in producing the *toute ensemble* of the senile debility. Where, however, the anatomical changes are pronounced the effect of the mental stimulus soon wears off through the fatigue following physical activity. Renewed stimulation will renew the mental and physical activity, but as the senile changes progress more powerful stimuli are required, fatigue sets in more rapidly, and the individual finds it more difficult to brace up. It is sometimes possible to produce the mental stimulation by drugs or other therapeutic agents, acting either as mental stimulants or by improving the physical condition. The most useful drugs for this purpose are phosphorus and arsenic. The theoretical objection to these drugs is that in large doses they produce fatty degeneration of the organs. This objection does not hold good when given in medicinal doses. I have never seen any deleterious results from either, although I have had patients take them for years. I might refer to the Styrian arsenic eaters who take that drug from childhood yet are generally long-lived and robust in old age. Phosphorus is a mental stimulant and nerve tonic having no cumulative effect, no reaction; its action is prolonged, it produces no habit, and there are no bad effects when its use is discontinued. It increases mental activity, producing a sense of well-being, making the individual more cheerful and causing him to take an interest in something else besides himself, sexual stimulation is sometimes produced, and there is a desire to do some work. Phosphorus is best given in solution. I prefer Thompson's solution in ten minim doses, given several times a day, stopping as soon as there is a noticeable change in the person's mental attitude. When there is mental depression again its use must be resumed, but with the increasing mental and physical debility the dose and frequency must be increased. I have lately used the non-toxic amorphorous phosphorus in grain doses without any appreciable effect. Arsenic improves the physical condition of the aged. It has a cumulative effect and it may cause serious results if used after the limit of tolerance has been reached. When given as a tonic it should be given in fairly large doses, say one-twentieth of a grain or six minims of Fowler's solution twice daily for two or three days then stopped for a week. Opium and its preparations are active cerebral stimulants when given in small doses, but the effect soon wears off and there is great danger of forming a habit. Some years ago an aged physician in this city began to take morphine in one-twentieth grain doses to overcome mental depression and failing memory. He soon regained his former brilliancy as a speaker, but he found it necessary to constantly increase the dose until, about a year later, he was taking one-third of a grain. He died some months afterward, supposedly from an overdose.

While the psychic form of senile debility may be overcome through psychic influence or drug action, and true senile debility in which the mental factor is prominent may be relieved by the same means, little can be done for that form of senile debility which is entirely due to anatomical changes. Phosphorus is useful if there is mental depression, but it has little or no effect in mental weakness. It has been suggested that this weakness is caused by the action of the macrophags upon the brain cells. If this supposition is correct then we must assume that morphine and similar substances that increase mental power also inhibit the destructive action of the phagocytes. Unfortunately the injurious effects of these drugs upon the organism more than counterbalance the benefit to the brain. Arsenic apparently increases bodily vigor and improves the appetite. The effect, however, is not lasting, and, owing to the altered gastric action in old age the effect of the first few doses must be carefully watched. One of the great difficulties in the treatment of senile cases is the determination of dosage, for we have to consider altered assimilation and elimination, the condition of the stomach, and the incidental effects of the drug upon degenerate organs and tissues. The aged generally tolerate comparatively large doses of arsenic, but occasionally we will find a case where two or three doses given in twelve-hour intervals will suddenly produce the effect of the combined dose. Arsenic, like phosphorus, should always be given in solution.

The measures to minimize waste of tissue are hygienic and dietetic. Some of these have been briefly referred to in a former paper.* The food should combine the maximum amount of nutritive value with the minimum amount of digestive effort, it should be as free as possible from lime salts, it should have no constipating tendency, and it should leave little waste. Physical activity should not be carried to the point of fatigue as the constructive

*Medical Record, Dec. 11, 1909: "The Treatment of Diseases in Senility."

metabolism proceeds much slower in old age than in earlier life and does not allow complete recuperation for excessive waste. Some physical activity must be included in the daily routine either as part of the person's daily labor or as a recreation. The recreation must be governed by the basic principle that recreation should be the antithesis of the work that requires it, mental labor requiring physical recreation, an active vocation requiring rest, etc. Attention must be paid to the excretions, whether there be disease or not.

The stiffness in the joints which the aged ascribe to rheumatism is due to hardening of the ligaments. We cannot give a scientific explanation for the beneficial effect of liniments in these cases; neither can we deny that liniments, massage, and other local measures do occasionally "limber up" the stiffened joints in old age. There seems to be some virtue in the old soldier's remedy, bad whiskey and castor oil, although the use of alcohol or fusel oil (amylic alcohol) is clearly irrational. The application of moist heat followed by massage is often of service; the effect is, however, only temporary. There are some incidental measures to retard the senile stoop and overcome the tendency to slouch. A cane should be used as soon as the aged person shows a tendency to stoop or slouch. It should be unyielding and so long that when the point is on the ground at the distance of the man's step from the body the man can grasp the handle without bending forward. Most canes are too short and the man must do the very thing that the cane is intended to prevent. A comfortable rocking-chair with broad arm rests should be provided. This and other apparently insignificant measures have a greater value than appears at first glance. The old man seated on a chair drops his hands in his lap. Seated in a rocking-chair with high back and broad arm rests he keeps his arms on these rests, thereby forcing his shoulders slightly back and allowing a somewhat better expansion of the chest. This may appear insignificant in maturity, but in senility, with impaired respiration owing to compression of the lung through the anatomical changes in the chest walls, and impairment of lung tissue, anything which helps to aid chest expansion without increasing muscular action is beneficial. Another important advantage of the rocking-chair is the position it allows the aged person to assume while dozing, especially after meals. In two cases death overtook aged persons while dozing after dinner, and in both cases the head had fallen forward and the persons were apparently asleep until found dead. It may be that these deaths were due to interference with the cerebral circulation, for if we sit in the dozing position with the head flexed upon the chest we shall notice in a few minutes the dull headache and flushed face of cerebral hyperemia. With the rocking-chair so poised that the head will fall backward instead of forward, this does not occur. While this is a matter of general observation I fail to find any reference to the effect of posture in sleep. If the heart and kidneys are in good condition a Turkish bath followed by an oil rub should be taken occasionally, but if either of these organs is diseased tepid baths followed by an oil rub must be substituted. Difficulty in walking is often due to broken down arch, one of the most frequent ailments of the aged. Arch supporters generally relieve this condition.

Two diseases closely associated with senile debility are senile dementia and senile tremor. There are two forms of senile dementia, one due to organic brain disease the other due to the ordinary senile brain changes. The latter is the true senile dementia, presenting a progressive mental enfeeblement with such irrational acts as arise from loss of memory, weakened reasoning power, and lessened restraint upon the emotions. The other form of senile dementia is a form of insanity such as may occur at an earlier age complicated by the progressive mental weakness of senility. In the latter cases there are evidences of organic brain disease, such as apoplectic or hemiplegic attacks, convulsions, temporary aphasia, vertigo, speech defects, irregularity of pupils, impaired reflexes, etc., with the symptoms of insanity, delusions, extravagances, mental confusion, and progressive mental weakness. Nothing can be done for this form of dementia except to combat symptoms as they arise. In true senile dementia marked improvement in the mental condition follows the use of small doses of morphine. The improvement is, however, only temporary, habituation is certain and rapid, the dose must be constantly increased to satisfy the craving for the drug, and death often occurs from an overdose. The temporary mental stimulation is accompanied by greater physical activity, but this passes away rapidly, leaving the body much weaker than before, the degenerative processes proceed more rapidly, thereby hastening the end. Senile tremor is often mistaken for paralysis agitans. There are absent in senile tremor the forward pitch, the cramps, the muscle stiffness (not to be confounded with the joint stiffness of senility), the deformity of the hands, the change in speech and voice found in paralysis agitans. In senile tremor the lower limbs are rarely involved except after fatigue, the tremor is bilateral from the start and the head and neck muscles are early affected. There is a coarse tremor of the head, a fine tremor of the lips and tongue, and a shaking of the drooping lower jaw. Drugs useful in other forms of tremor are useless in the tremor of senility. The bromides and iodides are contraindicated. While arsenic and strychnine are of benefit in the beginning, later the large doses necessary produce dangerous secondary effects. The debility that accompanies disease in old age increases the existing senile debility, and while the disease may be cured the increased debility remains. There are some ill-defined conditions in old age marked by excessive tissue waste and debility without pronounced symptoms of disease. Schoenlein's "marasmus senilis" and Hufeland's "marasmus senilis factitius" are of this character. The former is due to atrophy of the stomach and intestines, occurring in the course of the normal senile changes. In Hufeland's marasmus there is also an atrophy of the stomach ad intestines, occurring in precocious senility, following rapid child-bearing, excesses, and fast living. Senile tuberculosis may give no other manifestations than rapid emaciation and debility, but in this disease as well as in carcinoma, marasmus, and other wasting diseases the emaciation is so pronounced that the physician's attention is attracted thereto rather than to the accompanying debility, and he looks for a defined disease. As pathological processes hasten the normal senile processes and increase the senile debility, and as general asthenia is one of the two most frequent causes of death in old age, measures to overcome this should be taken from the outset of treatment of a senile disease.

ICHTHYOL IN PULMONARY DISEASES.

By WILLIAM S. BARNES, Ph.B., M.D.,

NEW HAVEN, CONN.

It is believed by the author of this paper that in ichthyol we have a safe and valuable remedy in the treatment of diseases of the respiratory tract and I refer principally to tuberculosis in the early stages, bronchitis in all its forms and pleurisy. As to pneumonia I have used the drug in only one case and that terminated fatally. On the other hand, I believe that all our cases of tuberculosis of the lungs and those disorders under suspicion should be given ichthyol as a means of bringing about a cure. My first experience with this drug in the treatment of tuberculosis was at the New Haven Dispensary in 1898. A patient came to the dispensary suffering from tuberculosis. He was in very poor condition. Physical examination, aided by the microscope, plainly demonstrated his condition. This case was put upon ichthyol and from the start began to improve. What we had considered a hopeless case was rapidly brought to such a state of health, that he soon returned to work and was again able to support his family. That this case showed a tendency to recover as evidenced partly by a remarkable diminution of the tubercle bacilli in the sputum showed that ichthyol acts as a curative agent and should, therefore, be tried in combating this disease.

Owing to the complex formula of ichthyol—and it is the ammonium salt to which I have reference—we are left to our own ideas as to what there is in the drug that has such a beneficial action. The therapeutists say that this drug is an alterative, contracting the blood vessels and acting as an intestinal antiseptic. I believe that the drug is rapidly broken up in the stomach and that it acts as a stimulant upon the gastric mucous membrane, promoting a larger flow of gastric juice and increasing the power of digestion, thus aiding in the assimilation of food. My reason for this supposition is that patients who have done well under ichthyol immediately begin to show a greater desire for food, and their appetites begin to increase with remarkable rapidity. In fact, my experience with the drug has convinced me that unless there is this immediate improvement in the desire for food it is unwise to continue the treatment. As to any further action of the drug, I believe that its bowel property as an intestinal antiseptic is generally considered to be its most active virtue. It is probably by this means that the fever is reduced; that is, the toxins are eliminated from the blood into the intestinal tract, where they are neutralized and prevented from being absorbed. It has been my experience that ichthyol, when given in large doses, will produce a tendency toward frequent movements of the bowels; and in speaking of large doses I have given as high as 20 grains three times a day, without any other effect than the bowel trouble. Whether or not any of the products into which ichthyol is decomposed are secreted by the mucous membrane of the respiratory organs the writer is unable to state. However, I believe that the drug does diminish the quantity of the discharge from the bronchial mucous membrane and hastens the return to a healthy condition, especially in those cases which have recovered from the acute bronchitis but still retain a cough accompanied by profuse expectoration. It is my rule in cases of bronchitis to use the ordinary expectorant mixtures, either ammonium chloride or terpin hydrate, combined with syrup, or in chronic cases to use potassium iodide. After using these remedies without obtaining definite results I prescribe ichthyol.

In the preceding remarks I have referred more particularly to the use and action of the drug in adults; but in the subsequent prescription of ichthyol as a treatment for bronchial affections in children I have learned to appreciate its value more. It is here that we see the alterative effect of the drug and the abatement of the bronchial coughs which do not yield to ordinary treatment. My experience with ichthyol in children began five years ago, since which time I have been using the drug quite freely. In the various text books upon children that by Jacobi is the only one that mentions ichthyol in the treatment of children. He speaks of Cohn, Scarpa, and Frenkel as eulogizing this drug. Holt says in 500 autopsies on children Muller found that forty per cent. had some tuberculous deposits and that 30 per cent. of the deaths were due to tuberculosis. In view of the foregoing fact is it not reasonable to suppose that many doubtful diagnoses of children's diseases might give way to one of tuberculosis?

In prescribing ichthyol for internal administration my practice has been to give it in solution, and because of its objectionable taste it is necessary to combine it with ordinary peppermint water, which makes it a fairly palatable mixture. Sometimes I add a small amount of fluid extract of licorice, together with peppermint water. It should be given after meals. A very convenient form of administration is to give it in the form of a tablet containing 5 grains. I prefer the drug given in the liquid form.

Before concluding this paper I wish to mention several cases taken from a large number which I have been able to observe after the treatment had been discontinued.

Case I.—Master L., aged 8. Family history good. Cough without expectoration. Loss of appetite. Slight rise in temperature in the evening. Frequent attacks of pleurisy over the right lung. Anemic. Moist râles over the right lung. No dullness. Examination of the sputum not made. Patient was given ichthyol, .10 c.c. after meals. In a short time improvement was noticed and eventually a cure resulted.

Case II.—Master B., age 12. Family history poor, mother having died of tuberculosis. Father's health good. This case was one in which all the active symptoms of phthisis were present, consisting of hemoptysis, daily temperature with evening rise and pain in the chest, and there was slight consolidation in both apices. The sputum contained a number of tubercle bacilli. Ichythyol in .25 gram doses was given. After several weeks the treatment caused the symptoms to abate and the patient, when last seen by me, was able to do light outdoor work.

Case III.—Miss R., age 16. Father died of tuberculosis. Mother living. Seen by me in August, 1901. Cough severe. Expectorated freely, sputum yellowish in color. Confined to bed by an attack of hemoptysis. Temperature at the highest, 103, in the evening. Tubercle bacilli in the sputum. No area of consolidation. Both lungs filled with crepitant râles. This patient recovered and has been at work in a factory in this city. Enjoys good health except in the spring, when she has a return of the cough, and then ichthyol is prescribed as before. I wish to mention in this case the remarkable demonstration of the increased assimilation of food. The patient always developed an enormous appetite under the use of ichthyol.

Case IV.—Mrs. J., age 35. Family history neg-

ative. History of cough and a previous acute attack. Temperature ran along 101 to 103. Diagnosis of acute bronchitis. Confined to bed. Patient given expectorants with no beneficial results. Expectorated large quantities of yellow sputum. Lungs negative. Pains in chest. Examination of sputum negative. Improved under ichthyol and is now enjoying good health.

Case V.—Child, male, age 2 years. Family history good. Cough was constant and bronchial tubes were filled with bubbling râles. Took very little nourishment. Child had frequent periods of rapid rise of temperature during the day. Anemic. No area of consolidation. This case did very well under ichthyol, being free from any lung difficulty when last seen by me.

Case VI.—Baby, 2 years old. Father and mother healthy. Three other healthy children in the family. Mother stated that the child had always been sickly. Child had a cough. Feverish every day. Moist râles in the chest. Loss of appetite and emaciation. Upon taking ichthyol child improved, the most noticeable improvement being the increase in appetite, the child simply craved for food. It was subject to frequent relapses, but always improved under treatment.

Case VII.—Child, age 3. Family history good. Mother said that child had had several previous treatments for obstinate cough with no apparent result. Examination of the chest was negative. Pulse and temperature normal. Child seen by me three years later, when mother stated that the child had done well under treatment, which had been ichthyol.

Case VIII.—Master J., age 4. Family history good. Mother said that child had coughed since he was a baby. Brought to this country from Denmark, where he had been under treatment. Cough was loud and rasping, being especially severe at night. Both lungs contained sonorous and sibilant râles. No fever. Iodides benefited the child for a time, but the cough returned when the drug was stopped. Ichthyol cleared the chest and showed remarkable alterative properties.

In closing permit me to state that the patients mentioned represent a variety of cases that certainly did well under ichthyol, and, while I do not wish to overestimate the value of this drug, I trust that I may influence others to try the drug in cases similar to those mentionad above. I am convinced that in ichthyol we have another drug that we may add to our list as a curative agent in the treatment of pulmonic disorders.

NONPARASITIC CYST OF THE SPLEEN; SPLENECTOMY.

By CYRENUS G. DARLING, M.D.,

ANN ARBOR, MICH.

CLINICAL PROFESSOR OF SURGERY IN THE UNIVERSITY OF MICHIGAN.

Nonparasitic cysts of the spleen seem to have been rare in this country, at least only a small number have been reported. Powers of Denver in 1906 reported a case which was treated by drainage because it was impossible to remove the tumor. This, I believe, is the first case reported in the United States. In 1908 Johnston wrote a paper on splenectomy, in which he states that only 19 of these cases had been reported in the literature in which splenectomy had been performed.

Since his paper, I have been able to find but two cases to add to my own, which is briefly as follows: Miss H., 18 years old, and a housekeeper, was well as a child, with nothing unusual in her family or personal history. She attended school the same as other children, graduating from the high school in June, 1909. Her trouble began in January, 1908, with pain in the left side just below the nipple line. The pain came suddenly and was so severe that the doctor was called the same day. Her temperature at that time was 102°. The pain was steady and extended upward to the left shoulder and arm. She was sick in bed about one week with a continued fever and sweating, the temperature at one time reaching 105°. On his second visit the doctor noticed an enlargement below the border of the ribs on the left side, which gradually increased for a time.

Four weeks later she was able to attend school and continued her work until the end of the term. During the summer she visited the doctor occasionally and he observed that the enlargement gradually diminished and remained much smaller. When she entered school again in the fall she was free from pain and felt very well. The doctor did not see her again for nearly a year. In July, 1908, she was examined by another physician because of a pain in the left side of the chest, and he made a diagnosis of intercostal neuralgia. He mentioned to her that he noticed the enlargement, but did not seem to consider it of much importance. He advised hot applications over the region of pain, which seemed to give great relief. Her own physician also examined her later in the month of July and found the mass quite small. The next examination was in October, when he found a very marked change, as will be described later. For three weeks she had been troubled with a pain in the left side, not constant, but increased by deep breathing. Until three days ago she did the family housework and three weeks ago did the family washing. I mention these facts to show the slight inconvenience arising from this growth.

When brought to me for examination, October 6, 1909, she had a feeling of fullness in the stomach. There was palpitation, but no irregularity of the heart on exertion. She slept well and had a good appetite. For the past year her weight has remained about the same, 155 pounds. Menstruation was regular until about four months ago, when the interval became shorter and the flow increased. During this time she had noticed no change in the growth. Examination shows a hard, smooth mass projecting below the border of the ribs on the left side to within two fingers' breadth of the umbilicus. The border is somewhat thin and contains a well marked notch. It displaces the liver and heart upward to about the fifth intercostal space, but recedes in the midaxillary line to the eighth rib. The line of dullness from in front posterior is sixteen inches, and from above downward, seven and one-half inches. From the sternum to the left along the rib border there was an ill-defined sense of fluctuation. A needle inserted at the outer end of this line and carried upward produced a syringeful of fluid for examination. This fluid was of a chocolate color, containing broken down and crenated blood corpuscles. Treatment with heat and nitric acid gave a large amout of albumin. No uric acid or cholesterin crystals were found. The blood examination showed 4,290,000 red blood cells and 6,000 leucocytes. Hemoglobin was 90 per cent.

Operation was performed October 10, 1909. This

was begun by an incision two inches to the left of the median line in front and extending from the rib border downward about six inches. About the middle of this line a three-inch incision was carried to the left through all of the tissues. This exposed the spleen with the cyst in the upper part. The cyst was opened and the contents removed, thus revealing the relations of the sac which was attached to the omentum and diaphragm by adhesions. The cystic portion had pushed the spleen proper downward so that the hilum could be easily reached and the vessels secured. The peritoneum at the hilum was opened and the vessels were ligated separately. The separation of adhesions from the diaphragm caused a considerable loss of blood but no sharp hemorrhage. Because of free oozing of blood, a large gauze drain was placed in the space from which the spleen was taken, and the wound was closed.

Like other cases of this type which have already been reported, this patient made a good recovery and is well at the present time, one year after the operation. One point which I considered might be of interest would be the blood changes incident to the removal of the spleen. This work was carried out by Dr. Washburn, who prepared the table which follows:

Day	Date	Hemoglobin	Erythrocytes	Leucocytes	Lymphocytes	Large mononuclear leucocytes	Polynuclears	Eosinophiles
2	9–8	90%	4,290,000	6,000	21%	4%	72%	3%
1	9–9	90%	4,750,000	7,300	19%	2, 5%	74%	4, 5%
0	9–10	*						
1	9–11	80%	3,937,000	9,600	16%	3%	74%	7%
2	9–12	80%	3,420,000	10,400	14%	4%	78%	4%
3	9–13	80%	3,280,000	11,200	†			
4	9–14	80%	3,400,000	9,400	19%	7%	60%	14%
5	9–15	85%	3,724,000	8,900	17%	5%	70%	8%
6	9–16	85%	3,800,000	8,500	†			
7	9–17	85%	3,750,000	8 000	†			
8	9–18	90%	4,000 000	8,700	13%	10%	70%	7%
10	9–20	90%	4,000,000	7,200	11%	7%	76%	6%
14	9–24	95%	4,700,000	8,200	15%	4%	72%	9%
18	9–28	95%	4,600,000	8,000	17%	6%	75%	2%
21	10–1	100%	4,700,000	7,500	19%	3%	73%	5%

*Day of operation. No count made.
†Differential, not made.

The table shows such blood changes as might occur in any operation of equal magnitude with considerable loss of blood.

Another point of importance in the recovery was the readjustment of displaced organs. For two or three days there was pain in the region of the heart and some catching of the diaphragm, particularly when the patient would turn on the right side. This soon passed away and at the end of three weeks the patient was sent home.

Krönlein's case developed temperature and a left-sided pleurisy on the eleventh day. Two weeks later 700 c.c. of clear fluid were taken from the pleura. A good recovery followed.

All reported cases of nonparasitic cyst of the spleen treated by splenectomy made a good recovery. This arouses one's interest. But examination of the histories shows a number of cases of wandering spleen in which the operation was simple. Also, if the cyst is of considerable size the gland itself is pushed downward so that the pedicle can easily be reached. Those operated upon have been selected cases. Powers was unable to do splenectomy because of adhesions, and selected the much safer procedure of drainage in this particular case. The size of the tumor depends largely upon the amount of fluid in the cyst, as the organ itself will, in most cases, show little change. Heurteaux reports a case in which the cyst contained 9 liters of fluid; Spencer Wells, one of 5 liters; Krönlein's case and the one here reported each contained 3½ liters.

Very little has been said about the origin of these cysts. Monnier's paper has taken up the subject from various points, but his conclusions are indefinite. He found that of 14 cases, 12 were women and 2 were men. He did not consider this the result of chance or injury, but rather associated with the periodical changes and hyperemias which women experience during menstruation and pregnancy.

Some can be closely associated with trauma, others vaguely so, and still others have no such relation. I was not able to find the slightest evidence of injury in my case. The changes noticed in the menstrual function were not present until long after the appearance of the tumor. The appearance of the sac and contents would lead one to believe that the cyst was formed by hemorrhage. Why the hemorrhage? The pathologist must answer that.

107 South Main Street.

Radiotherapy in Affections of the Spinal Medulla.—G. Marinesco presents the results of his study of the treatment of affections of the spinal medulla by means of radiotherapy. He treated in this way three patients suffering from sclerosis in plaques, the rays being used over the cervical region and on the lumbar region, for 7 to 10 minutes. There were no skin effects in any of the patients. He got good results in one case in relation to motor disturbances, tremor, scanning speech, spastic gait, and disturbances of urination. The painful spasmodic contractions experienced at night were lessened. There are many facts with reference to animal experimentation and treatment of human beings that go to show good effects of radiotherapy in nervous diseases. The effect of the rays on young immature cells is remarkable. Some fragile cells in the young when the adult age is reached become indifferent to the rays. In some tissues they produce a proliferative action. The constant influence of the rays on all adult tissues and their karyokinesis is known. In nerve, gland, and muscle cells the activity of multiplication is reduced. Most of the inflammatory diseases of the spinal medulla are amenable to radiotherapy. In acute affections in which the nervous parenchyma is already altered radiotherapy cannot give good results. But in subacute and chronic diseases, and in certain tumors, great service is rendered. Aside from the diseases in which the rays destroy pathological elements, such diseases as sclerosis, Aran-Duchenne atrophy, etc., they are valuable also where they are used to stimulate altered nutrition of nervous elements.—*Annali di Elettricità Medica e Terapia Fisica.*

Infantile Malaria.—Jean P. Cardamatis says that during the nursing period infants are less liable to malarial infection than at any other age, and the months of least liability to infection are below three months. Morbidity is less under one year of age than later. As to the transmission of the hematozoa through the placenta, the author has made studies in connection with Pezopoulos and has concluded that the organisms do not pass through the placenta from the mother. The cases in which tests were made were twenty in number, and in all of them severe attacks of malarial fever were present, with many organisms in the blood on the maternal side of the placenta. The blood of the infants a few hours after labor showed no organisms. The blood in the liver and spleen of two infants that died showed no organisms. In five cases in which the blood was examined on the fetal and maternal sides of the placenta no organisms were found on the fetal side. None were found in the blood of the cords of children. Paludism in infants may be acute and chronic; the chronic form is more frequent, on account of failure of diagnosis in the acute stage. The chill is less pronounced than in the adult, and is accompanied by vomiting and convulsions in many cases, while the stage of sweating is lacking. The spleen is much enlarged in the chronic form, and the cachexia is marked, the child having the appearance of a wax figure in color of skin. Anemia is severe.—*Archives de Médecine des Enfants.*

New York, January 21, 1911.

THE DISORDER OF MEDICAL CHARITY AND ITS REMEDIES.

THE abuses associated with the vast amount of gratuitous medical service rendered to the public have, for a long time since, evoked the just protest of those who take time to consider the economic hardships which indiscriminate medical charity inflicts on the rank and file of the profession. In spite of the floods of eloquence that have been poured forth in condemnation of this evil, no adequate remedies have yet been applied or even suggested. The problem has never been approached with that analytic skill which the physician displays in unraveling the tangled meshes of disease. The glamour of the word "charity" has blinded the eyes of the generous practitioner to the injustice with which it is so frequently allied. For this reason modern methods of organized charity have been practically ignored in the lavish distribution of free medical aid.

Amid economic conditions even more stringent than those prevailing in this country, our British colleagues have felt more keenly the sharp tooth of man's ingratitude. It is quite natural, therefore, that the investigation of this subject should appeal more strongly to the English practitioner. Rarely has it been approached with such comprehensive thoroughness and deep insight into facts as in the address delivered by Lauriston E. Shaw before the Stratford Division of the British Medical Association, November 3, 1910, and published in the *Lancet*, December 24, 1910. As physician to, and lecturer on medicine at, Guy's Hospital, he is qualified to apply to this subject the faculties of the trained observer. The method of orderly analysis is at once discerned in the classification of medical charity. There is the individual internal medical charity, which is one of spirit rather than of action, which one member of the profession may extend to his colleague. Then there is the question of collective internal medical charity, the organization of a scheme of mutual medical benevolence by means of which the profession may deal with those cases in which sickness or early death throws its members or their dependents upon the indulgence of the community. Similarly external medical charity is divided into individual and collective. In regard to the former, the physician will be guided by his conscience in dealing with the needy who appeal to him for help. But promiscuous private charity, like promiscuous public charity, is one of the most fruitful causes of the failure of suitable provident schemes whereby such poor people could secure, without the pain of charity, adequate provision in time of need.

It is to the question of collective external medical charity that Dr. Shaw's address is chiefly directed. He finds from convincing indications that this form of medical charity is excessive, without order, ineffective, and obstructive. The mere excess of the volume of medical charity is a splendid tribute to the quality of heart of those who are responsible for it. The imperative call of physical suffering and impending death does not appear to be the sole cause of this excessive supply. The latter is largely occasioned by the fact that there is no form of charity that the philanthropist can purchase so cheaply. By endowing with five thousand dollars a bed in a surgical ward, he can look forward in every year, forever more, to providing for seventeen patients, each securing a first-class operation at the hands of a skilled surgeon, the visits of the latter two or three times a week, the visits twice a day of a house surgeon, the help whenever needed of radiographers and other specialists, and the constant attendance of nurses. No one can blame the philanthropist for laying out his money to such advantage, but the pertinent question is propounded, "why can every philanthropist who thinks of building a hospital or founding a dispensary be confident that he can secure unlimited medical service free of cost?" It is usually assumed that the physicians who render this service receive in return for it "experience, advertisement, and honor." This is only too true. But the experience referred to is enjoyed by a favored few. In the public interest arrangements should be made for the privileged class freely to share this experience with their less-favored brethren by securing constant cooperation between the staffs of hospitals and the practitioners engaged in private practice amongst the neighboring population. A ring or corner in medical experience cannot be for the common good.

It is trenchantly remarked that the peculiarity of advertisement by charitable medical practice is that the obvious and first cost is borne, not by the advertiser, but by his less-prosperous colleagues, to whose possible patients he gives free service. Besides, patients too honorable or too simple to seek charitable assistance at the hospital are often seriously crippled financially by the high fees which surgeons find themselves obliged to charge because of the large amount of free treatment given to others often far better able to pay.

There is a want of coordination between different medical charities and between these and other agencies that provide medical assistance, such as systems of health insurance. The third great defect of medical charity is its failure to restrict its benefits to the proper recipients. This is a particularly difficult phase of the subject, for one naturally revolts at adding any unnecessary physical or mental trouble to a patient in pain or discomfort by inquiring as to his economic fitness.

In suggesting a remedy for these abuses, Dr. Shaw states that it must not interfere with any State scheme for dealing with the immediate treatment of the very poor, nor with any of the provident schemes of health insurance. It must recognize the partnership of medical charity, medical education, and medical research, and must foster a continuance of this association. The remedy proposed is as follows: Medical charity should provide the help corresponding to the consulting practitioner, refusing in any case to deal at first hand with patients, but freely offering assistance to those who, in the usual way of private practice, by some provident system, or through the State, have secured the services of a medical attendant to deal with ordinary ailments and are found by him to require and to be unable to pay for further assistance. This is a definite aim which it is thought would at once eliminate the greater part of overlapping and would enable charity satisfactorily to coordinate its activity with all other agencies for medical relief. After alluding to other advantages of his most original and novel plan, unfortunately too Utopian for this age and generation, Dr. Shaw concludes that the great force which will finally direct medical charity into this definite field of activity is the public spirit of the medical men responsible for the work. Those who possess the extraordinary advantages conferred by hospital appointments will not tolerate the continuance of a system which brings them "experience, advertisement, and honor," at a heavy cost to their less-fortunate colleagues, and hopelessly blocks the way to numerous urgently needed reforms in the medical treatment of the sick poor.

THE COMMON METHOD OF INFECTION IN HUMAN AND BOVINE TUBERCULOSIS.

Sir John McFadyean, principal of the Royal Veterinary College, London, in his presidential address to the Section of Comparative Pathology and Veterinary Hygiene of the Birkenhead Congress in 1910, discussed the common method of infection in human and bovine tuberculosis. The conclusions he drew were as follows: (1) The inhalation of tubercle bacilli suspended in the atmosphere is a very certain method of infection in susceptible animals even when small doses of bacilli are employed. (2) Experimental infection with tubercle bacilli by way of the alimentary canal is comparatively difficult to realize even in highly susceptible animals, and success is certain only when very large doses of bacilli are administered. (3) With few exceptions in animals experimentally infected with tuberculosis by way of the intestine the primary lesions are intraabdominal and the intrathoracic lesions, when present, are secondary. (4) Inhalation is, probably, the commonest natural method of infection in man and cattle in which the primary lesions of tuberculosis are usually intrathoracic. (5) Naturally contracted cases of tuberculosis in man and other mammals can be ascribed to infection by ingestion only when the lesions revealed at the post mortem examination are confined to the abdomen, or when the existing abdominal lesions are recognizably older than those present elsewhere in the body.

McFadyean points out that the whole of the experimental evidence on which the theory of the intestinal origin of pulmonary tuberculosis in man was built up has been swept away and valuable new support has been provided for the older inhalation theory, but one ought to avoid the mistake of denying any importance to infection by ingestion either in man or cattle, or of asserting that tubercle bacilli, which enter the body by way of the alimentary canal, are never the cause of tuberculosis with lesions apparently primary in the lungs.

PHYSICIANS IN GERMANY IN 1910.

The total number of medical practitioners in the German empire for 1910 was 32,440, a slight increase over last year, but no actual increase when compared to the total number of inhabitants. This ratio has for ten years past varied but little (from 5 per 10,000). Of the total number nearly 2,000 were military and naval surgeons. There are almost 200 women practitioners in the empire. The number of medical students seems to be constantly increasing, but the surplus of these appear to find their way into foreign lands, so that the domestic ratio is not affected. A study of individual localities does not appear to reveal the existence of any law. There is a moderate decrease of men in Berlin, while Bremen shows a slight increase, and Hamburg remains stationary. If we regard 5 per 10,000 as the universal average, it is easily seen that the cities, as a class, invariably exceed this figure. Wiesbaden excels with 22.6 per 10,000. Munich has 16.6, Greater Berlin, 12.3, Cologne 9.8, Leipzig 8.3, Hamburg, 7.7, Chemnitz, 5.6, and therefrom downward. These figures must be evened up by those obtained from rural districts and the smaller cities.

Of especial interest is the increase in women physicians and in specialists. The former have come up from practically nothing to nearly 200 per 10,000 in a relatively short time.

Even more interesting, perhaps, is the increase in special practitioners, especially in large cities. When notation as to specialization began, say in 1906, 20 per cent. of metropolitan or urban practitioners were recorded as "specialists." Since that date there has been a considerable increase. At the same time the number of specialties has been declared, no less than twenty-seven forms of practice being included. Going beyond nominal specific practice the author includes many more which represent an actual specification of methods or subjects. He concludes that over 60 per cent. of practitioners are specialists at least as the larger towns are involved.

An Antivaccination Revival.

A resident of Richmond Borough has recently aroused fresh interest in the subject of vaccination against smallpox by refusing to allow his two children to be vaccinated as required by the Board of Health before they can attend a public school. Not

satisfied with the barring of the children from school which resulted he has publicly announced that they are not receiving a proper education at home in order that the Board of Education may be compelled to take up the matter under the compulsory education law. His supporters assert that the Board of Education should provide at least one school in each borough to be attended by those children whose parents are opposed to vaccination. From Brooklyn comes an offer of $1,000 to any hospital which will furnish five physicians who are willing to submit first to vaccination and then to an injection of smallpox virus, the sum to be paid provided at least 60 per cent. of them do not contract the disease. These incidents have stirred up once more Mr. Poultney Bigelow, who writes to the *New York Times* a detailed account of his recent sad experience with vaccination. He was sweet and bonny on leaving Yokohama only a few short weeks ago, filled with love and longing for his native land. But somebody said smallpox, and a German doctor, who by some foul chance was in medical charge of an American ship, rushed into the first cabin and "injected" all the passengers with "a poison which he called vaccine." And so the joyfully anticipated homecoming was spoiled. Mr. Bigelow's "head was racked with pain;" his "tongue resembled a kitten;" he "was in high fever;" his "digestive organs became inoperative," and his "throat seemed to be in a demon's clutch"—symptoms, some might say, suggestive rather of overindulgence in the pleasures of the smoke-room than of cowpox. He finally tottered down the gangplank at Honolulu and sought refuge among friends, with whom he remained a month, slowly building up "the strength which a hellish superstition had undermined by pretending that vaccination is good for society." Mr. Bigelow is well known as a sanitarian. It was he who spent a few minutes once on the Isthmus and came away with his risibles excited by what he thought was Col. Gorgas' silly fetch at sanitation in putting up mosquito netting. He is so funny we can't spare him and can only be thankful he did not fall a victim to vaccination, this "manifestation of stupid superstition, as silly and cruel as many a priestly practice of medieval Europe"—whatever that may mean.

Clinical Value of the Cammidge Reaction.

Dr. Lyell C. Kinney, resident physician at the German Hospital, Philadelphia, writes on the Cammidge reaction in the *American Journal of the Medical Sciences* for December. The urinary examinations, originally proposed by Cammidge in the *Lancet*, March 19, 1904, for diagnosis of disease of the pancreas have been performed repeatedly in the laboratory of the German Hospital with unsatisfactory results. Both "A" and "B" reactions were tried and discarded. The failure of these reactions tended somewhat to create a feeling of scepticism as to the value of the "C" reaction. A fifteen months' trial, however, has been given the "C" reaction, and according to Kinney has caused the investigators to believe that it has a somewhat limited value, although negative reaction does not indicate that the pancreas is normal, for negative results have been obtained in acute and chronic pancreatitic carcinoma and cyst of the pancreas. Further, a positive reaction is not pathognomic of pancreatic disease, as the reaction is found to be positive in some cases in which there is no evidence, even to direct palpation that the pancreas is not normal. However, Kinney goes on to say, if history, physical examination, and examination of the feces point to the presence of a pancreatic lesion, we may consider a positive Cammidge "C" reaction to be of value in completing the diagnosis. In other words, very little dependence can be placed upon a negative reaction and a positive reaction can be considered of value only as a confirmation of other signs.

News of the Week.

The Women's Medical Association of New York City will hold a meeting to honor the memory of Dr. Elizabeth Blackwell and Dr. Emily Blackwell, at the New York Academy of Medicine, 17 West Forty-third street, at 8.30 o'clock on Wednesday evening, January 25, 1911. Addresses will be delivered by Dr. Stephen Smith, Mrs. Henry Villard, Miss Alice Stone Blackwell, Dr. Abraham Jacobi, Dr. William H. Welch, Dr. Gertrude B. Kelly, Dr. William M. Polk, and Dr. Emma B. Culbertson.

The New York Hospital.—After long negotiations the New York Hospital, one of the oldest institutions of its kind in the United States, has announced the purchase of a block of land lying between Fifty-fourth and Fifty-fifth streets and Eleventh and Twelfth avenues, Manhattan, on which it will shortly erect a group of modern hospital buildings. The hospital is the first to locate along the Hudson River front, and has secured an almost ideal site, since only a line of piers will intervene between it and the river, while to the south the De Witt Clinton Park extends for several blocks. Plans for the building will be prepared by Messrs. McKim, Mead & White of New York. It is not likely that the new hospital will be ready for occupancy before January, 1915, and no decision as to the disposal of the old site will be made for the present. The New York Hospital dates back to the time of King George III, the first building having been erected in 1773 on the corner of Church and Worth streets. A fire destroyed the structure before it was completed, and the hospital was given a public grant of 4,000 pounds sterling to enable it to continue. The Revolution then broke out, and it was not until January, 1791, that the hospital finally opened its doors for the reception of patients, the unfinished structure having been used as a barracks by British and Hessian soldiers during the war. In 1869 a new hospital was planned; the work was temporarily abandoned owing to lack of funds, but later through income derived from its real estate, the society was able to erect the present buildings on Fifteenth street, which were opened in 1877. These buildings are now being almost completely shut in by skyscrapers The New York Hospital Society also maintains the House of Relief on Hudson street, and the Bloomingdale Hospital, and a home for convalescents at White Plains, 60,000 to 70,000 patients being treated annually.

Summer Courses in Medicine.—The College of Physicians and Surgeons, Columbia University, New York, will offer, during the summer of 1911, laboratory courses in clinical pathology, bacteriology, physiological chemistry, and nutrition, and at Bellevue Hospital a course in physical and medical diagnosis. With the exception of the last the

courses are open to both men and women, and all will count toward the degree of M.D. for students in the college. Particulars can be obtained from the secretary of the university.

Charitable Bequests.—The Red Cross Hospital of New York receives, under the will of the late William T. Wardwell, a bequest of $100,000, payable upon the death of the testator's widow, on condition that the hospital continue the methods of treatment now in practice with regard to the non-use of alcohol as a medical agent, and that the use or other narcotics and of drugs which might induce a habit or produce injurious after effects be reduced to a minimum. The will provides that the question as to whether the hospital has observed the terms of the bequest is to be submitted to a board of three arbitrators, one chosen by the hospital, one by the executors, and one by the other two. The hospital also receives some money to be used in paying off its deficit.

Dr. Albert Seessel of New York, who died on December 24, left a bequest of $1,000 to St. Mark's Hospital of that city. The residue of his estate, which is estimated to amount to about $100,000, is left in equal shares to Yale University and the Königsliche Sachische Gesellschaft, Leipzig, Germany, to establish a fund in memory of his mother for the promotion of original research in biology.

The Plainfield, N. J., Anti-Tuberculosis Society receives a legacy of $5,000 under the will of the late Mrs. George L. Babcock of that city who died recently.

The Convalescent Home for Children at Thun, Switzerland, receives an income of 3,000 francs a year by the will of the late Baroness von Zedtwitz disposing of her property in this country.

Mount Sinai Hospital, the German Hospital, and the Montefiore Home, New York, each receives $500 under the will of the late Ludwig Rothschild of New York.

The Nursery and Child's Hospital of New York inherits $10,000 under the will of the late John W. Ellis who died in New York recently.

St. Luke's Laboratory.—With a greatly increased equipment, made possible by a generous endowment, the new laboratory of St. Luke's Hospital, New York, has recently been opened. Some changes have been made also in the personnel of the laboratory staff, which now includes Dr. Francis C. Wood, Director; Dr. Karl M. Vogel, Clinical Pathologist; Dr. J. Gardner Hopkins, Bacteriologist; Dr. William H. Woglom, Pathologist; Dr. George C. Freeborn, Assistant in Pathology, and Dr. N. B. Foster and Dr. H. O. Mosenthal, Assistants in Chemistry.

Associated Physicians of Long Island.—The annual meeting of the society will be held in the Library Building of the Medical Society of the County of Kings, 1313 Bedford avenue, Brooklyn, on Saturday, January 28, at three o'clock. Dr. John B. Deaver of Philadelphia will read a paper on "The Value of Surgical Diagnosis in Upper Abdominal Disease," and Dr. Charles Eastmond one on "Abnormalities of the Colon as Demonstrated by the *X*-ray." After the scientific session the officers for the coming year will be elected and installed. This will be followed by a dinner at the Hamilton Club, at which Dr. Charles F. Stokes, Surgeon General of the Navy, will be the guest of honor and will speak on "The Navy and the Important Relations to the Naval Establishment Borne by the Medical Corps." Dr. D. Bryson Delavan of New York, and Dr. John C. MacEvitt, retiring president of the County Medical Society, will also speak.

Dr. Edsall Resigns.—The resignation of Dr. David L. Edsall from the professorship of medicine in the University of Pennsylvania has been announced. Dr. Edsall has accepted the chair of preventive medicine at Washington University, St. Louis, which was offered to him a year ago. At that time, in order to keep him in Philadelphia, the University promoted him from the chair of pharmacology and therapeutics to that of medicine. His acceptance now of the earlier offer indicates that Washington University promises more attractive opportunities for the student of scientific medicine.

Hospital Alliance Approved.—At a meeting of the trustees of Columbia University, on January 9, the proposed alliance between the College of Physicians and Surgeons and the Presbyterian Hospital was unanimously approved. The details of the agreement by which the University will have the right to nominate the entire staff of the hospital and by which the latter will receive a large sum of money for the erection of new pavilions to be used for laboratory and teaching purposes, have been left in the hands of a special committee of the trustees, the representatives of the hospital, and Mr. Harkness, who has made the gift which makes the alliance possible.

St. Barnabas' Guild.—The twenty-fifth annual service of the New York branch of St. Barnabas' Guild of Trained Nurses was held on the afternoon of January 8, at the Church of the Heavenly Rest, Bishop Greer of New York presiding. The guild at present contains about 150 members, including the superintendents of a number of New York hospitals.

Benefit Entertainmet.—An entertainment given for the benefit of the National Jewish Hospital for Consumptives of Denver, Col., on January 8, in New York, netted about $3,500.

The Carnegie Laboratory.—Through the generosity of Mr. Andrew Carnegie a large addition to the Carnegie Laboratory of the University and Bellevue Hospital Medical School, New York, has been built, and was opened with appropriate exercises on January 10. Among the speakers were, besides Mr. Carnegie, Dr. William H. Welch, Dr. H. M. Biggs, and Mr. Jerome D. Green, general managers of the Rockefeller Institute. Considerable interest was aroused by Mr. Carnegie's intimation during the course of his remarks that an appeal for further funds for the use of the school would not find him indifferent. Dr. Egbert Le Fevre, dean of the medical school, presented to Mr. Carnegie, on behalf of the laboratory staff, four beautifully bound volumes containing the researches in medical science published from the laboratory during the last few years.

Infantile Paralysis.—Passed Assistant Surgeon W. H. Frost of the Public Health and Marine-Hospital Service has been detailed to investigate and report on the occurrence of cases of infantile paralysis in New York State during 1910. Dr. Frost, who recently conducted a similar investigation in Iowa, will work in conjunction with the State Department of Health.

Combined Medical School.—The Gross and University of Colorado Medical Schools, which were recently merged through the adoption of an amendment to the State Constitution, opened as one institution on January 1. The junior and senior

classes will be held in Denver, while the first two years will be given at the University of Colorado, in Boulder.

Education by Billboards.—During the next few months 20,000 educational billboard posters will be sent broadcast through the United States by the National Association for the Study and Prevention of Tuberculosis. The National Billposters Association has donated free space, the Poster Printers Association has offered free printing, and nine paper manufacturers have given the paper for the posters, for which six different designs have been prepared. In graphic form the posters are to show how fresh air, good food, and rest cure tuberculosis how bad air, overwork, and closed windows lead to it; and how the careless consumptive menaces the health of his family by spitting.

Plague in China.—Because of the spread of bubonic plague through Manchuria, a conference of physicians of the foreign legations and missions and a number of Chinese was held recently, and it was decided to recommend to the Government the institution of a five days' quarantine of first-class passengers at the Great Wall, and the immediate cessation of second and third-class passenger traffic. It is feared that the Russians may object, owing to the injury that such action is likely to cause the Trans-Siberian Railway.

Fire in Hospital.—While the temperature stood at 26° below zero, the Walker Hospital, at Walker, Minn., was almost completely destroyed by fire on January 2. Twenty patients were removed from the building without injury.

Eddy Healer Arrested.—For the purpose, it is said, of making a test case, a Christian Science "practitioner" was arrested recently in New York charged with practising medicine without a license. The district attorney will be assisted in the prosecution of the case by the New York County Medical Society.

New York Pathological Society.—At the annual meeting of the society held at the Academy of Medicine, on January 11, the following officers were elected to serve for the ensuing year: *President,* Dr. William G. MacCallum; *Vice-President,* Dr. John H. Larkin; *Secretary and Editor,* Dr. A. M. Pappenheimer; *Treasurer,* Dr. Francis C. Wood. Dr. T. M. Prudden and Dr. E. K. Dunham were reelected trustees of the society to serve for a term of three years. The next meeting will be held in conjunction with the Philadelphia Pathological Society in Philadelphia on February 9.

Bellevue Hospital Alumni.—The Society of the Alumni of Bellevue Hospital will celebrate the twenty-fifth anniversary of its founding on Tuesday, February 28. There will be reunions of the various staffs in the rooms at the hospital during the afternoon with visits to the old wards with the old officers, and inspection of the new buildings and their equipment. In the evening a reception will be held followed by a banquet.

University of Pennsylvania.—Announcement has been made of the gift from an alumnus of the University of $100,000 for the endowment of the Benjamin Rush Professorship of Physiological Chemistry, the first incumbent to be Professor Alonzo Englebert Taylor, at present Professor of Physiological Chemistry.

Etowah County (Alabama) Medical Society.—At the meeting held at Gadsden, on January 4, the following new officers were installed: *President,* Dr. H. V. Baskin; *Vice-President,* Dr. J. E. Leach; *Secretary and Treasurer,* Dr. William C. Williams.

Belmont County (West Virginia) Medical Society.—At the annual meeting held in Bellaire recently the following officers were elected for the ensuing year: *President,* Dr. B. O. Williams, Martins Ferry; *Vice-President,* Dr. V. N. Marsh, Flushing; *Secretary,* Dr. J. S. McClelland, Bellaire; *Treasurer,* Dr. A. C. Beetham, Bellaire.

Reading (Pennsylvania) Medical Society.—The following officers were elected at the meeting held on December 30: *President,* Dr. H. F. Rentschler; *Vice-President,* Dr. F. G. Runyeon; *Secretary,* Dr. J. L. Wagner; *Treasurer,* Dr. Clara S. Keiser.

Chattanooga and Hamilton County (Tennessee) Medical Society.—At the annual meeting held in Chattanooga on December 30 the following officers were elected: *President,* Dr. James H. Atlee; *Vice-President,* Dr. Frank T. Smith; *Secretary-Treasurer,* Dr. H. P. Latimore.

Hettinger County (North Dakota) Medical Association.—At a meeting of the physicians of the county held in New England, on December 30, plans were made for the formation of a medical association, and the following officers were elected: *President,* Dr. J. W. Stribling, New England; *Vice-President,* Dr. J. Hamilton, Bentley; *Secretary-Treasurer,* Dr. F. T. Rucker, Mott.

Marion County (West Virginia) Medical Society.—The election of officers, held on December 30, resulted as follows: *President,* Dr. James W. McDonald, Fairmont; *Vice-President,* Dr. H. O. Rohrbach; *Secretary,* Dr. H. R. Johnson, Fairmont; *Treasurer,* Dr. William H. Sands, Fairmont.

New York Neurological Society.—Officers for the year 1911 were elected recently as follows: *President,* Dr. L. Pierce Clark; *Vice-President,* Dr. Smith Ely Jelliffe and Dr. Edward W. Scripture; *Corresponding Secretary,* Dr. J. Ramsay Hunt; *Recording Secretary and Treasurer,* Dr. Edwin G. Zabriskie.

Muscogee County (Georgia) Medical Society.—Officers were elected at the annual meeting held on December 14, in Columbus, as follows: *President,* Dr. H. Stokes Munroe; *Vice-President,* Dr. Gordon Chambers; *Secretary,* Dr. Stewart Murray; *Treasurer,* Dr. B. W. Allen.

Cass County (Iowa) Medical Society.—At the annual meeting held in Atlantic on December 15 the following officers were elected: *President,* Dr. T. B. Morris, Atlantic; *Vice-President,* Dr. Thompson, Marne; *Secretary,* Dr. Max Emmert, Atlantic.

Des Moines County (Iowa) Medical Society.—The following officers were elected at the annual meeting held in Burlington on December 14: *President,* Dr. J. N. Patterson; *Vice-President,* Dr. W. W. Milligan; *Secretary,* Dr. E. F. La Force.

Polk County (Iowa) Medical Society.—At the annual meeting held in Des Moines on December 20 the following officers were elected for the ensuing year: *President,* Dr. O. J. Fay; *Vice-President,* Dr. S. E. Lincoln; *Secretary,* Dr. T. F. Duhigg; *Treasurer,* Dr. Nellie S. Noble.

Peoria City (Illinois) Medical Society.—The regular annual meeting was held on December 20, officers for the ensuing year being elected as follows: *President,* Dr. A. L. Corcoran; *Vice-Presidents,* Dr. W. B. Short and Dr. J. H. Ulrich; *Secretary-Treasurer,* Dr. E. W. Oliver.

Knox County (Indiana) Medical Society.—The following officers were elected at the annual meeting held on December 13 at Vincennes: *President,*

Dr. W. H. Davenport; *Vice-President*, Dr. E. T. Small; *Secretary*, Dr. C. S. Bryan.

Harrison County (Mississippi) Medical Society.—At the annual meeting held in Gulfport on December 15 the following officers were elected for the ensuing year: *President*, Dr. G. F. Carroll, Biloxi; *Vice-President*, Dr. D. G. Mohler, Gulfport; *Secretary-Treasurer*, Dr. B. Z. Welch, Woolmarket.

Newton-Neshoba-Winston County (Mississippi) Medical Society.—At the annual meeting at Newton on December 13 the following officers were elected: *President*, Dr. J. N. Whittle, Union; *Secretary-Treasurer*, Dr. J. A. Majure, Dixon.

Adams County (Nebraska) Medical Society.—The following officers were elected at the annual meeting held at Hastings on December 14: *President*, Dr. J. W. Straight; *Secretary-Treasurer*, Dr. E. A. Weir.

Buncombe County (North Carolina) Medical Society.—Officers for the ensuing year were elected at the annual meeting at Asheville on December 19 as follows: *President*, Dr. C. E. Cotton, Black Mountain; *Vice-President*, Dr. H. H. Briggs; *Secretary-Treasurer*, Dr. C. S. Tennent.

Canadian County (Oklahoma) Medical Society.—At the annual meeting of the society held on December 17 the following officers were elected: *President*, Dr. R. F. Koons; *Vice-President*, Dr. S. S. Sanger; *Secretary-Treasurer*, Dr. J. T. Riley.

Santa Clara County (California) Medical Society.—At the annual meeting, held on December 21, officers for the ensuing year were elected as follows: *President*, Dr. Jonas Clark; *Vice-Presidents*, Dr. W. S. Van Dalsem, Dr. Harry C. Reynolds, and Dr. J. L. Hogg; *Secretary*, Dr. W. T. McNary; *Treasurer*, Dr. H. J. B. Wright.

Allen County (Kansas) Medical Society.—The following officers were elected at the annual meeting held in Iola on December 21: *President*, Dr. J. W. Bolton; *Vice-President*, Dr. A. J. Fulton; *Secretary*, Dr. O. L. Cox; *Treasurer*, Dr. F. H. Martin.

Christian County (Kentucky) Medical Society.—The annual election was held in Hopkinsville on December 26, officers for the ensuing year being chosen as follows: *President*, Dr. O. E. Wright, Bolivar; *Secretary*, Dr. W. S. Sandbach, Casky.

Eighth District (South Dakota) Medical Society.—At the meeting held on December 23, at Yankton, the following officers were elected: *President*, Dr. Koobs, Scotland; *Vice-President*, Dr. Melgaard, Volin; *Secretary-Treasurer*, Dr. Roane, Yankton.

Hunt County (Texas) Medical Society.—At the annual meeting on December 22, at Dallas, the following officers were elected: *President*, Dr. Edwin P. Becton; *Vice-President*, Dr. T. B. Spaulding; *Secretary-Treasurer*, Dr. J. A. Bush.

Johnson County (Texas) Medical Society.—At the annual meeting held at Cleburne on December 22 the following officers were elected for the ensuing year: *President*, Dr. J. H. Meason, Rio Vista; *Vice-Presidents*, Dr. Prestridge, Alvarado, and Dr. Lee Yater, Cleburne; *Secretary-Treasurer*, Dr. Washburn, Cleburne.

Rock County (Wisconsin) Medical Society.—At the annual meeting held in Beloit on December 27 the following officers were elected: *President*, Dr. G. W. Fifield, Janesville; *Vice-President*, Dr. W. H. Allen, Beloit; *Secretary-Treasurer*, Dr. E. B. Brown, Beloit.

Utah County (Utah) Medical Society.—The annual meeting of the society was held in Provo on December 21, officers for the ensuing year being elected as follows: *President*, Dr. David Westwood, Provo; *Vice-President*, Dr. O. E. Grua, Pleasant Grove; *Secretary-Treasurer*, Dr. H. G. Merrill, Provo.

Seventh District (Wisconsin) Medical Society.—At the annual meeting held on December 22, at La Crosse, the following officers were elected for the ensuing year: *President*, Dr. E. H. Townsend, New Lisbon; *Vice-President*, Dr. E. F. Christian, La Crosse; *Secretary*, Dr. C. H. Marquardt, La Crosse.

The Late Dr. Alexander.—The following "In Memoriam" of Dr. Samuel Alexander was presented by the committee appointed for that purpose at the last meeting of the Society of Alumni of Bellevue Hospital:

The Society of Alumni of Bellevue Hospital has learned with profound regret of the untimely death of Dr. Samuel Alexander. Dr. Alexander was born in New York City, April 2, 1858. After a short and sudden illness he died in New York on November 27, 1910. He was graduated from Princeton University, receiving the degree of Master in Arts in 1879. In 1882 he was graduated from Bellevue Hospital Medical College. He served on the house staff of Bellevue Hospital from 1882 until the spring of 1883. After leaving the hospital he pursued his studies in European clinics for two years. He then returned to this country and entered actively his special field of work. In 1887 he was appointed Attending Surgeon to Bellevue Hospital, which position he filled until the time of his death. From 1889 until 1898 he was Professor of Genitourinary Surgery at Bellevue Hospital Medical College, and from 1898 until his decease he was Professor of Genitourinary Surgery at the Cornell University Medical College.

Dr. Alexander was one of the most earnest and enthusiastic members of this society. He was elected its vice-president in 1897 and he served as its president in 1898-99. He was always most constant in his attendance and energetic in promoting the best interests of this organization. Dr. Alexander's ability in his chosen field of work was preeminent and his researches made him distinguished not only in this country but also throughout Europe. His genial manner and ready command of language rendered him remarkably successful as a teacher, and his unselfish and warm-hearted disposition endeared him to all those who knew him. The Society feels that in his death it has suffered the loss of one of its most distinguished members who, from its earliest days, did much to bring it to the position it now occupies. In commemoration of its loss and of the sorrow it feels, it directs that this tribute to his memory be spread upon the minutes and that a copy be sent to his family, and that it be published in the medical press. Signed:

PARKER SYMS,
REGINALD H. SAYRE,
ALEXANDER LAMBERT.

Obituary Notes.—Dr. DARWIN COLVIN of Clyde, New York, a graduate of the Geneva Medical College in 1844, a member and in 1887 second vice-president of the American Medical Association, formerly president of the New York State Medical and of the Wayne County Medical Societies, and of the Central New York Medical Association, a surgeon in the 107th New York National Guard during the

Civil War, died at his home, on January 8, aged 88 years.

Dr. Laban L. Bradshaw of New York, a graduate of the Bellevue Hospital Medical College in 1880, a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Physicians' Mutual Aid Association, and the Lenox Medical and Surgical Society, died at his home, on January 9, aged 58 years.

Dr. Edward Paulding of New York, a graduate of the Bellevue Hospital Medical College in 1890, died at his home in Flushing after a brief illness, on January 10, aged 48 years.

Dr. William Wolfe Lesem of New York, a graduate of the College of Physicians and Surgeons, New York, in 1903, and a member of the American Medical Association and of the New York State and County Medical Societies, died suddenly of apoplexy, on January 11, aged 32 years. Dr. Lesem was at one time on the staff of the Post-Graduate Hospital and at the time of his death was in the Out-Door Department of Mt. Sinai.

Dr. William A. Oberle of Newark, N. J., a graduate of the Baltimore Medical College in 1907, died at St. James' Hospital in Newark, on January 6, of blood poisoning, aged 28 years.

Dr. Allison O. Douglass of Little Falls, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1877, and a member of the American Medical Association and of the New York State and Herkimer County Medical Societies, died at his home of pneumonia on January 11.

Passed Assistant Surgeon John Flint, United States Navy, a graduate of the Harvard University Medical School in 1903, died at the Naval Hospital in Boston, where he was on duty, on January 11, aged 34 years.

Dr. Robert H. McCamy of Philadelphia, Pa., a graduate of the University of Pennsylvania Medical Department, in 1879, and a member of the Pennsylvania State and Philadelphia County Medical Societies, died at his home, on January 5, aged 55 years.

Dr. Alfred M. Critz of Seattle, Wash., a graduate of the Department of Medicine of the University of Indiana in 1877, died suddenly at his home, on December 28, aged 58 years.

Dr. John Abbott Prince of Springfield, Ill., a graduate of the University of Michigan Department of Medicine and Surgery, Ann Arbor, in 1887, and a member of the Illinois State and Sangamon County Medical Societies, died suddenly, on January 1, aged 47 years.

XMAS IN THE HOSPITALS—MEASLES—606—MALARIA—SEA-SICKNESS—OBITUARY.

London, December 30, 1910.

Xmas has been celebrated in the hospitals as enthusiastically as possible, and the resident staffs have taken a large part in providing the entertainments. At hospitals for children the Christmas tree has been prominent, but Punch and Judy shows, conjuring, magic lantern and cinematographs have made an appearance, while Santa Claus and Father Xmas piled the tables with generous gifts from supporters, toys, dolls, and all sorts of things. In some the children contributed carols and various songs. In the general hospitals the adult as well as children's wards were equally provided for, and here, too, the resident doctors took a large part in setting up and carrying out entertainments. In one or two I have heard of, perhaps in others also, they produced a farce or other dramatic piece in which the performers earned as much applause as star artists, as well as the gratitude of all the patients who were able to form the audience.

Measles has been rather prevalent of late and the notificationists accordingly active. An inquest held yesterday will no doubt set them in full cry. The subject was a little girl of 2¼ years, who died in St. Bartholomew's Hospital, to which she had been taken on account of severe scalds while she had measles, for which her mother said she gave her saffron in milk. The Coroner, Dr. Waldo, who usually speaks with consideration, said it was wonderful how ignorant women were about measles, which was the most deadly of all the catching complaints. There had been, he continued, a frightful death rate from it in London during the last few months, and saffron, or brandy, seemed the notion of a British mother as to what was needed. The house physician supported the Coroner, said the child's death was due to bronchial pneumonia following scalds and measles, describing this as the most fatal of all infectious diseases, though cases were not usually admitted to the hospitals. A verdict of accidental death was returned, the jury adding a rider that notification should be compulsory, hospital treatment given to the poor, and every case followed by proper cleansing and disinfection of their premises.

Many problems of hygiene, etc., are thus raised. In large towns the children of the masses have to run the gauntlet of contagion in the first quinquennium, and those who escape that period are almost sure to meet an epidemic during school life. Adults who have escaped now and then take it later. But is it, after all, so deadly? That many die is to be expected if practically the whole population are attacked. General practitioners mostly regard it as of slight importance in healthy children unless complications occur. There were 90 fatalities last week in London, which is 56 above the average, showing that it is still prevalent, and this does not show the ratio of deaths to cases, and these must have numbered many thousands.

Continuing my gleanings on 606 from last week, I may remark, in a preparatory way, that I have since seen a medical man who was injected three months ago and who tells me that from that day he has been a different man. The injection gave severe pain, but he cared nothing for that. He had suffered for years at intervals and was extremely sensitive to mercury, which he had tried in many forms, always with temporary relief, but always obliged to interrupt the treatment. At the time of injection he was greatly depressed, could hardly do any work in a satisfactory way. The operation seemed to lift a heavy weight from him and he is no more gloomy and oppressed with a sense of impending evil. This case seems to confirm an impression that the new remedy has proved most useful in cases intolerant of mercury and those affecting the central nervous system.

Dr. McDonagh, whose paper at the Harveian Society I have previously cited, has also related his experience at the West London Society and dis-

cussed some additional reports. He referred to cases which had been described of sleeping sickness, tubercular leprosy, a leukemia, psoriasis, and lichen planus, in which benefit had been observed. This seemed more decided in cases which might be regarded as complications, as when streptococci or staphylococci, or even tubercle bacilli were superadded to the original disease. Cases were exhibited to show the curative effect of 606; one in which extensive phagedena had been checked; one of tabes in which the Argyll Robertson pupil had disappeared and the knee jerks returned. Dr. McDonagh had treated 130 cases altogether, three recurred but two were cured by a second injection. Only five cases gave no response.

Captain L. W. Harrison, R. A. M. C., said that 606 had been in use for some months at Rochester Row Military Hospital. It had usually been given by intravenous injection, an ordinary transfusion apparatus being employed with a pointed needle. A second dose had been administered when clinical signs did not clear up rapidly or if Wassermann reaction remained positive after three or four weeks.

Dr. Bayly regarded the evidence as to Wassermann reaction as very conflicting and the permanency of the effects of 606 as by no means established.

Dr. Etherington-Smith spoke of the immediate results in several cases as really wonderful and related one of gummatous meningitis of 10 years' standing which was remarkable.

Dr. Grainger Stewart did not think the nervous manifestations likely to be benefited by 606 and in this view Mr. McDonagh appeared to concur, though he said that early cases of G. P. I. had certainly improved.

Mr. C. F. Marshall, who has had considerable experience, wrote in the *Medical Press* a fortnight ago, that there was no proof that an abortive cure had been effected by 606 and he added that relapses are common and some cases are refractory. He further asserted that the new remedy had no effect on parasyphilitic lesions, which are the most dangerous. He refers to the many contraindications admitted by Ehrlich and, indeed, all observers, concluding with a suggestion that we should think twice before recommending 606 to patients. I have not ascertained whether he is disposed to modify his opinion.

When the Royal Society admits papers on medical subjects it is, of course, from the scientific point of view that they must be dealt with. This month there have been important communications on malaria and on sleeping sickness by such authorities as Ronald Ross, David Thomson and others. These two have reported a minute coordinated study of malarial cases, almost daily estimates of the number of parasites being made, as well as frequent estimates of the leucocytes, hemoglobin, and excreted urobilin. Dr. G. E. Simpson also contributed a preliminary note on hemoglobin metabolism in this disease. He found more urobilin excreted by the feces than by the kidneys. This was remarkably so in a case of blackwater fever, where there was an amount of urobilin representing the destruction of all the hemoglobin though the amount in the urine was small.

On sleeping sickness Ross and Thomson reported further observations on a case related in a previous paper. The trypanosome cycle then described continued until death. The fever was greater during the trypanosome increase, so were the total leucocytes and in the fall they continued to increase. Atoxyl in doses of 2 to 4 grains, quinine and methylene blue in large doses had no appreciable trypanocidal action. The effects of subcutaneous injections of trypanosome and of leucocytes were further studied.

The same authors reported experiments on the treatment of infected animals by atoxyl, vaccines, cold, *x*-rays, and leucocytic extract. Regular daily counts of the parasites in the peripheral blood were made. Atoxyl in small repeated doses seemed to prolong the life of rats infected with the Rhodesian strain of the parasites, for these increased rapidly by active division, as if the drug stimulated division and it seemed to be a tonic to the body cells of the host. It required almost lethal doses to kill the parasites and these did not permanently cure as resistant bodies were formed. Vaccines, cold, *x*-rays, and leucocytic extract gave uncertain results in various respects.

The sudden death of Dr. William Hoffmeister, aged 67, on Wednesday, removes a notable personage from the Isle of Wight, where for 40 years or more he had been surgeon to the Royal Yacht Club and where, also, he had held other offices, including the Medical Officership of Health. He was surgeon to Queen Victoria and the royal family in the Island, and a member of the Victorian order.

Dr. Thomas P. Fothergill, J. P. for Yorkshire, died on the 23rd inst., aged 67. He qualified in 1864 and graduated at Edinburgh, M. B., 1865, and M. D., 1867.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

FIFTIETH ANNIVERSARY OF BERLIN MEDICAL SOCIETY —HISTORY OF THE SOCIETY—HONORARY MEMBERS —ETHICAL CONSIDERATIONS CONCERNING 606.

BERLIN, December 15, 1910.

On October 26 the Berlin Medical Society celebrated its fiftieth anniversary. Since this is the largest and most important of the German medical societies, a short report of this celebration would be of interest. The hall of the Langenbeck memorial building, in which both the German Surgical and Medical Societies meet, was at the unusual hour of midday filled with the members of the Medical Society, upon whom gazed the wreathed portraits of its late presidents, Graefe, Langenbeck, Virchow, and Bergmann. The first oration upon the history of the society was delivered by the President, Senator. He stated that the medical society had been formed by the union of two other societies, the Society of Scientific Medicine, founded in 1844 by Virchow, and the Society of Physicians of Berlin, founded in 1858. The number of members had grown from 204 to 1,611. The society flourished under Virchow, who not only carried it to a high scientific level, but also placed it in good financial circumstances. In 1867 the society acquired legal rights, and for the past eighteen years has been the part owner of its building. Some concern for its future development was occasioned when in 1881 the Society of Internal Medicine was founded by Frerichs and Leyden. Nevertheless, through the wise efforts of Langenbeck, the welfare of the Medical Society was not compromised by the new organization. Nor was the establishment of the societies of the various specialties of any detriment to the larger body, whose steady growth proved its value as a forum for both scientific workers and

practicing physicians. There followed a series of felicitations by Rubner, the rector of the University; Ziehen, the dean of the medical faculty; Bier, the president of the German Surgical Society; Kraus, representing the Society of Internal Medicine; Stöter, representing the Physicians' Guild; Alexander, representing the Practitioners' Societies, and Mayet, the Society of Social Medicine.

The capacity of the meeting hall and of the library have become inadequate, and for a long time there has been proposed the erection of a new building, to be named in honor of Rudolf Virchow. According to the secretary, the funds available for this purpose have reached a substantial sum, but not sufficient to warrant beginning to build on the chosen site. Further contributions for this purpose are to be sought. Then the vice-president, Orth, announced the election of Senator as honorary president, a distinction that had already been enjoyed by Langenbeck, Virchow, and Bergmann. The following were made honorary members: S. Exner, Vienna; E. Fuchs, Vienna; C. Golgi, Rome; Armauer Hansen, Bergen; A. Jacobi, New York; F. von Koranyi, Budapest; W. W. Keen, Philadelphia; S. Kitasato, Tokio; C. L. A. Laveran, Paris; A. Lépine, Lyons; J. Lister, London; A. Murri, Bologna; S. P. Pavlov, St. Petersburg; S. Ramon y Cajal, Madrid; M. G. Retzius, Stockholm; C. J. Salomonson, Copenhagen; J. Boas and W. Kessler, Berlin, who have belonged to the society since its foundation, besides Waldeyer, Naunyn, and Röntgen.

The evening session was attended in even greater numbers, including the wives of the members. The largest auditorium in Berlin, the Philharmonie, could not accommodate the entire gathering. At long tables sat the members and invited guests, all united under the spell of music and jovial song. Considerable success greeted a drama written by Peyser, in which the medical society of the future was pictured, and which was ably presented by physicians.

Ehrlich's great discovery has during the past few weeks raised a ferment in the medical circles of Berlin. The manner of distribution of 606 has put certain physicians under a disadvantage, while others have profited. As soon as the public read in the daily papers of the success attending the use of 606, they stormed the physicians whom they knew had the remedy, with the resulting profit of the latter and the loss of those who had not been so fortunate as to get a supply. Therefore the business committee of the Berlin practitioners' societies proposed for discussion to the separate societies the following resolutions: 1. Remedies that have not yet been tested therapeutically should be available only in hospitals and clinical divisions. Their distribution for use in private practice should be avoided. 2. It is unethical for physicians to report their experiences with new remedies in the public press. These resolutions were rejected by all the societies. Above all, from the very beginning Ehrlich has been guided by the best intentions. Large amounts of 606 have been given gratuitously to physicians at home and abroad for experimental purposes. Naturally not all requests could be satisfied. If the general free distribution of the remedy has been somewhat delayed, this is to be attributed to the fact that no method has yet been devised by means of which 606 may be produced in large quantities. Only after arduous individual labor can a small quantity be manufactured, and in order that the first great demand may not wipe out the entire supply it is desirable that a large quantity should first be prepared. The rejection of the above mentioned resolutions was therefore to be expected, for laws that are framed on account of abuses, or that concern a few individual cases, are to be regarded as failures. Furthermore, the individual physician is not to be considered incompetent to judge and to test new remedies. The second resolution was surely superflous, for the practice therein mentioned has never prevailed in Germany, and never will prevail.

Progress of Medical Science.

The Prevention and Treatment of Typhoid Fever with Antityphoid Vaccine. F. F. Russell.
Antityphoid Inoculation as Introduced into Certain Training Schools for Nurses in Massachusetts. M. W. Richardson and L. H. Spooner.
The Fresh-Air School. J. Perkins.
The Care and Management of the Tabetic Bladder. III. Prognosis and Treatment. J. D. Barney.

Antityphoid Inoculation.—F. F. Russell states that the following conclusions seem to be justified: Typhoid has invariably appeared in armies in the past and may be expected in the future. The usual prophylactic measures are only partially available in camps. Vaccination is simple and harmless, and wherever used has reduced the incidence and mortality of typhoid. The immunization of every individual in the army is perfectly feasible, and it offers the greatest hope of freedom from this plague in the future. Antityphoid vaccination has long since passed the experimental stage. Since 1904, 60,000 men have been vaccinated in India, over 7,000 in Southwest Africa, and over 14,000 in the United States, and in no case has any harm followed its administration. The time has come when its use should be extended, not merely in the military services, but also among the civil population.

Antityphoid Inoculation in Nurses' Training Schools. M. W. Richardson and L. H. Spooner relate their experience, which covers 1,588 inoculations practised upon 405 individuals. As yet there have been no untoward results, and the authors believe that the inoculated individuals have acquired an increased resistance to typhoid infection which will last them for several years at least. They expect in the coming year to extend the influence of these inoculations, especially among nurses and others attendant upon the sick. Furthermore, they have strong faith that the procedure will, within a short time, find increasing favor with the general public, which, exposed as it is to many sources of infection, is in great need of specific protection.

The Fresh-Air School.—J. Perkins states that we have the data necessary for a consideration of the relation of the public schools to tuberculosis. Children who are affected with tuberculosis are in the schools and must be in the schools. They are there as arrested, as apparently cured, or as latent cases, and, just as with the patients who leave the sanatoriums, whether they go on to complete recovery or whether they are to enter the hospitals and add to the already enormous burden of hospital maintenance, or prematurely enter the cemeteries and thus be a loss to the State as individuals upon whom the State has already spent considerable money, will depend to a large extent upon their environment and the teaching they receive in the schools. The object of the fresh-air school is to have the air of practically the same purity as the out-of-door air and at the same time have the ingress of fresh air so regulated that the exposure of all the pupils and in all parts of the room will be practically the same. That this is perfectly feasible, even in the New England winter climate, without undue exposure of the children, has been demonstrated for three winters in Providence, and the same fact is now being demonstrated in various other

places, one of the best schools now being located in Pawtucket. The author alludes to the fresh-air school as a part of the regular school system and not as applied to patients who are actually sick. School work with these patients is being carried on somewhat in day camps, in sanatoriums, and in hospitals for tuberculous children.

The Tabetic Bladder; Prognosis and Treatment.—J. D. Barney concludes that infection of the urinary tract occurs in over 50 per cent. of patients with tabes dorsalis. The mortality from such an infection is nearly 60 per cent. Catheterization and irrigation of the bladder, at regular and frequent intervals, combined with the constant use of an efficient urinary antiseptic, will (a) delay, prevent, or reduce the activity of urinary infection; (b) postpone the appearance of residual urine, or diminish its amount if present; (c) relieve symptoms. Re-education of the muscles of micturition, combined with local treatment, will cure or relieve most of the symptoms which harass the life of the tabetic. It is, therefore, of the utmost importance. The combined treatment of the nervous system and of the urinary tract is essential for the welfare of the patient.

End Results of Surgical Operations on Nervous Women. S. T. Rucker.
Report of a Case of Diphtheria of the Vulva in a Child Three Years of Age. L. L. Smith.

Treatment of Gonorrhea in Women.—By H. J. Boldt. (See page 130.)

Primary Sarcoma of the Appendix.—C. A. Powers states that during late years systematic examination of removed appendices shows that in a not inconsiderable number those thought to be simply the seat of chronic inflammation prove to be malignant. Harte, in 1908, considered this subject in a most thorough way, gathering 111 cases of primary carcinoma. As result of this investigation he concludes that primary carcinoma of the appendix is present in from 0.3 per cent. to 1 per cent. of all cases operated on for chronic appendicitis. It is evident from this that every appendix removed should be submitted to careful microscopical examination. Primary sarcoma of the organ, however, is doubtless of great rarity. Harte, including in his list one instance of endothelioma, collected five cases from the literature. The writer is permitted to say that in about 7,000 specimens examined at the Rochester Clinic there was not an unquestioned case of primary sarcoma of the appendix found. The author reports a case occurring in a female patient 17 years of age.

Nervous Affections in Relation to the Eyes.—G. T. Stevens discusses, with a concrete example, the mental condition of children who, so far as can be seen, have normally developed bodies, with crania of favorable form and of average development. This class constitutes a very large and, he believes, a very hopeful proportion of the mental defectives. That there is very frequent and intimate connection between the adjustments of the eyes of this class of persons and the backward mental state experience demonstrates beyond a doubt. The author had already called attention to this relation and to the great benefits which might arise from appropriate treatment directed to the conditions of the eyes. He reports a case of imbecility in a girl of 15 in whom careful study revealed a very high grade declination of each eye. Objects seen are never still, never twice alike, always in confusion. The things of which she hears and the things which she feels are different from the whirling, unsteady things which she sees. Her senses are thus confused and, as she can not depend on them, the mind is also confused. If the confusion of senses were relieved the mind would work more true. This child had been examined in respect to her refraction and was using appropriate glasses. The examination had not been carried far enough. The oculist who tests the refraction and then tries a few, not illuminating, experiments with a little glass rod before one eye of his patient and supposes that he has examined the adjustments of the eyes has not even entered into the subject of such an examination. In this case, a month of painstaking examinations with the phorometer, the tropometer, the clinoscope, and other intruments, accompanied by patient attempts to instruct the patient, resulted in only the most moderate success, but such moderate success, when combined with observations upon the facial expression and bodily pose, observations based upon those of many hundreds of other cases, enabled a diagnosis to be made which proved to be correct.

Optic Nerve and Cranial Malformation.—A. Gordon reports the case of a boy 8½ years of age which is considered important from several standpoints. It is an example of an oxycephalic head (steepleshaped) with predominant pathological changes in the visual apparatus. The deformity of the skull noted from early infancy, probably as a result of inflammatory disturbances in the meninges and bones caused by a series of infectious diseases, was followed by gross basilar changes. The sphenoid bone, the most important of the basilar bones, contains all the foramina through which pass the blood-vessels and nerve fibers of the visual apparatus. Ophthalmic involvement was the natural and logical consequence of the deformation of the cranium. Exophthalmos, which is almost a constant accompaniment of oxycephaly, was present in the author's case. A very interesting condition was revealed by an *x*-ray examination of the skull. Contrary to the usual radiographic pictures of the brain and skull, here the contour of the entire brain with its individual convolutions and fissures was distinctly seen. The condition was probably due to a special thinness of the skull. While the patient presented no mental enfeeblement or disturbance, he nevertheless had attacks of generalized epilepsy. The latter was, probably, due to bilateral pressure on both motor areas caused by the abnormal or premature synostosis of the parietal bones. If one take into consideration the views of Virchow and Hirschberg, one may admit the existence of an old pachymeningitis in both hemispheres which is a sufficiently valid cause for an irritation of the motor areas and, therefore, for convulsions. The latter contention is highly plausible in view of the continuous severe headache of which the patient complained.

Twilight Talks with the Doctor.—G. F. Butler discourses on the subject of the physician's attitude and methods in the examination and treatment of children. He concludes that with proper skill and tact, active reliable remedies and proper methods of administration, one will find that his practice in diseases of children will be very pleasant and satisfactory, and remunerative; and if, as the family physician, one can teach parents how to so bring up and care for their children that they will not become physical, nervous, mental, or moral wrecks, one will be a public benefactor.

Theory of Trachoma.—H. M. Wandless presents the following as the principal lines of thought embodied in his paper: 1. That trachoma is nonspecific and noncontagious; 2, that follicular conjunctivitis and trachoma are one and the same disease; 3. that pannus must be regarded

as reparative, 4, that trachoma is essentially chronic and self-limited in its nature; 5, that predisposition and susceptibility are important causative factors; 6, that trachoma may be caused by one or more of a number of agencies; 7, that digestive disturbances including autointoxication are potent in the cause of trachoma; 8, that errors of refraction deserve careful consideration as contributing causes of trachoma; 9, that adenoids of the nasopharynx and trachoma are similar processes; 10, that heredity, which has been practically excluded from causation, is undoubtedly an important factor. He concludes that it is apparent that the whole treatment of trachoma as well as the whole trend of the disease from beginning to end supports in no undecided way a nonspecific, noncontagious theory. Lymphoid degeneration of the conjunctiva, as promulgated in his paper, may not wholly be accepted; the author is convinced, however, that his general ideas will stand. He feels that his presentation of this theory is justified by the fact that hitherto all investigations into the cause of trachoma have been along the line of microorganisms. For half a century failure has attended every effort to establish a specific theory, and it is high time that investigation in the opposite direction be undertaken.

Eosinophilia and Anaphylaxis.—E. Moschcowitz refers to the striking analogy between the phenomena of experimental anaphylaxis and such diseases as asthma, hayfever, and urticaria. The latter frequently coexist in the same individual. They are all included in the so-called "exudative diathesis" of Czerny and Strümpell. This diathesis may be regarded as anaphylactic in character. The phenomenon of anaphylaxis has also been applied to other conditions as follows: Eclampsia, the local tuberculin reactions, pellagra, drug susceptibility, exophthalmic goiter, migraine, tetany, and epilepsy. A feature common to all the diseases which the author has mentioned, and to which attention has not been drawn, is that they are all associated with an eosinophilia. In asthma, hayfever, and urticaria the blood contains an excess of eosinophiles; the secretions of the bronchus and of the nose in asthma and hayfever, respectively, are filled with eosinophile leucocytes. In urticaria, also, eosinophile cells are abundant in the wheals. Eosinophilia in the other manifestations of the "exudative diathesis" is a well recognized phenomenon. An eosinophilia, both local and general, is found in nearly all skin lesions (*e.g.* eczema, prurigo, Dühring's disease, pemphigus, psoriasis, etc.). In mucous colitis eosinophiles constitute the majority of the leucocytes in the excretion. In pellagra Neusser found the eosinophiles increased in the blood. Ewing, Da Costa, Neusser, Meyer, and Zappert, all describe an increase of eosinophiles in the blood after an injection of tuberculin. The occurrence of eosinophilia in helminthiasis is one of the recognized diagnostic features of this disease. In Graves' disease the eosinophiles are increased. In tetany, hemicrania, and epilepsy eosinophilia has been noted by a number of observers, especially by Neusser and Ewing. It is well known that eclampsia is associated with eosinophilia. In connection with the association of many of the manifestations of the exudative diathesis in "neurotic" individuals it is significant that Neusser and others have shown that eosinophilia is a common finding in such individuals. The conclusion is drawn that the increase of eosinophiles in the blood and the local manifestations must bear some relation to anaphylaxis. The invasion of eosinophiles in increased numbers into the organism is the expression of an active agent or the agent itself in the production of anaphylaxis.

Recurrent Insanity.—M. Talmey states that a patient may have an attack of mania or melancholia, recover completely, and remain sane all through the rest of his life. Whether such a case is to be classed with recurrent insanity—manic depressive insanity—or not, is merely a theoretical question. Practically it is of importance that in a given case of mania or melancholia with no history of previous attacks the physician should be guarded in the prognosis, bearing in mind the possibility of a recurrence of the disease, especially when a strong hereditary taint can be established in the family. In cases, however, in which there is a history of previous attacks, the physician is undoubtedly dealing with recurrent insanity and may predict other attacks with a fair degree of probability.

Operations on Nervous Women.—S. T. Rucker concludes that nervous women, as a rule, do not make good subjects for surgical operation. An operation should not be undertaken, unless there is a definite, unmistakable pathological lesion that is the chief cause of the nervous symptoms. A correct estimate of the end results of surgical procedures cannot be made unless the surgeon keeps in touch with his patients for months after they return home. In clearing up diagnoses in obscure conditions, every surgeon should seek the aid of a competent internist, neurologist, and pathologist. Last, but not least, to no one is the golden rule more applicable than to the surgeon. When a patient presents herself she seeks relief from suffering. She is not especially anxious "to be cut, but to be cured," and the surgeon should always ask himself the question, "If this was I, my wife, my daughter, would I advise an operation?"

Diphtheria of Vulva.—L. L. Smith reports a case of this condition in a child 3 years of age.

Vaginal Cesarean Section in Eclampsia.—R. Peterson contributes this article, which was reported in MEDICAL RECORD, Vol. 78, page 38.

Treatment of Eclampsia.—E. B. Cragin and E. T Hull contribute this paper, which was reported in MEDICAL RECORD, Vol. 78, page 38.

Etiology of Eclampsia.—E. P. Davis and C. Foulkrod present this study, which was reported in MEDICAL RECORD, Vol. 78, page 38.

Surgical Treatment of Eclampsia.—J. B. De Lee discusses this subject in an article which was reported in MEDICAL RECORD, Vol. 78, page 38.

Prevention of Infant Mortality.—G. Koehler and C. St. C. Drake remark that the infant mortality rate stands as a test for real sanitary accomplishment. With advancement in civilization the infant death rate should decrease, but this is not so much the case as it should be. The infant mortality rate has remained stationary or undergone no material reduction parallel with that in the general mortality. The authors give the results of a study of the statistics, with tabulated statements of the birth rate, death rate, and infant mortality rate for different periods in the principal countries; also the death rates of infants at various ages and an analysis of the infant mortality in Chicago with its age distribution. This shows that approximately 7 per cent. of infants dying during the first

year die in less than twenty-four hours after birth, with an average age of 4 hours and 41 minutes; 14 per cent. in from one to seven days; 53 per cent. in from seven days to six months, and 26 per cent. in the second half year of life. Out of an approximate total of 152,500, 20,013, or 131 per thousand, died before completing their first year. The author finds that children of Lithuanian, Polish, Hungarian, Bohemian, Italian, and Austrian mothers die in greater ratio than children of other nationalities, and, unfortunately, the rate of the last decade has not shown a proportionate decrease from that of the previous one. The statistics show also that greater progress in prevention has been made against the contagious diseases than against the chief cause of infant mortality, the diarrheal troubles. The general improvement in market milk is found not to give a milk supply suitable for young infants, though there has been a marked reduction in the bacterial contents. There has been, however, in the last years, since pasteurized milk has been more generally used, a marked reduction in deaths among babies. The tendency to urban concentration increases infant deaths. The preventive measures suggested are, first, those that directly influence the mother, the improved education, better environment, etc. School instruction may reach the future generations, but the present generation is more difficult to reach. Personal work with the mothers, as practised in some European countries, is suggested. Causes operating directly and indirectly on the child that require correction are incomplete birth registration, improper care, and neglected morbidity. Midwives require instruction as to their duties, and a correspondence school for midwives is operated by the Department of Health in Chicago with good results. The indirect causes, such as bad sanitation and housing, crowding, filthy environment, flies, bad water and milk, etc., are to be combated everywhere, bad milk and bad air especially. High-grade milk is often too costly for the poor, and infant milk depots have been established and are doing good work, though often they are utilized too late. The general market supply should be improved, and all milk not produced in accordance with strict sanitary requirements should be properly pasteurized under municipal control. Pure water should be supplied for infants during the hot season. Many infants suffer from unrelieved thirst, and air, the first requirement of the child at birth, should be pure.

Cactus Grandiflorus.—R. A. Hatcher and H. C. Bailey report experiments made with authentic samples of *Cactus grandiflorus*, and conclude that they have been unable to obtain any evidence that the true Mexican *Cactus grandiflorus* possesses any pharmacological action whatever, but, on the contrary, it appears to be a singularly inert substance when administered either by the mouth or by the vein. When colossal doses of *Cactus grandiflorus* are given by the vein they sometimes—but not always—appear to exert an extremely feeble action on the heart; but this action is so slight that its nature could not be determined. Even the most colossal doses administered by the mouth to cats, dogs, and frogs exert no perceptible effect.

Stimulation and Inhibition of Tissue Cultivation.—A. Carrel and M. T. Burrows state that the plasma of a sarcomatous animal acquires the property of inhibiting the growth of a sarcoma taken from another animal. If the inhibition is caused by substances secreted by the tumor and contained in the blood of the sarcomatous animal it seems that it might be possible to give that inhibiting power artificially to normal plasma by adding to it serous extract of sarcoma. The experiment was tried, but the growth of sarcoma was markedly accelerated instead of inhibited. This showed that the inhibiting power was not due to substances secreted by the tumor. Then, it is possibly caused by substances produced by the organism as a reaction against the tumor. The tumor belonging to the animal which has given the plasma is not affected by these inhibiting substances. The authors found that normal plasma becomes stimulated by the addition of a little sarcomatous extract and embryonal spleen was exceedingly sensitive to the action of the extract. They had already observed that the growth of cartilage could be stimulated by a fragment of quickly growing spleen and that a new culture of spleen is activated by the addition of a little piece of spleen in full growth. This suggested that all actively growing tissues of connective and other types contain a stimulating substance, but they found that fragments of spleen cultivated in plasma with tumor and embryonal extract showed that the tumor extract had a much more energetic stimulating power than embryonal tissue extract.

Growth in Vitro of Sarcoma.—R. A. Lambert and F. M. Hanes present a preliminary study which indicates that cultural methods may be easily adapted to the experimental investigation of transplantable rat and mouse tumors.

Gangrene of Appendix and Omentum.—R. R. Richardson reports a case of this condition which shows that a serious condition of affairs may exist in the abdomen before any symptoms are observed; and even when symptoms do make their appearance, they are by no means indicative of the severity of the condition causing them. The symptoms in this case would not have led one to think that such a widespread gangrenous condition was present in the abdomen.

Blood Transfusion.—A. H. Curtis and V. C. David enumerate the difficulties of the Crile method of transfusion, the delicate technique involved, the time consumed, the impossibility of measuring the rate of flow and amount of blood transfused, the liability to accidents by movements of the donor or recipient, and of transmission of infection to the donor, and describe a method which they think largely avoids these difficulties. It requires, besides mosquito forceps and vessel clamps, one 100 c.c. Porges ground glass or metal Y cannula. The studies of Freund and Bordet and Gengou have shown that blood introduced into vessels coated with oil or petrolatum remains uncoagulated for several hours. Advantage is taken of this fact in the method described. The syringe and cannula are sterilized by the dry method, fitted together under aseptic technique, and uniformly warmed over a flame. About 25 c.c. of sterile hot petrolatum is then aspirated into the apparatus, and, after the latter is thoroughly and rapidly coated by working the piston up and down, the excess is forcibly ejected through the ends of the cannula. The median basillic or other prominent vein of the elbow region is now exposed in both donor and recipient for a distance of 2 to 3 inches. The vein of the recipient is ligated at the end toward the hand, stripped of blood toward the heart, and a rubber-protected vessel-clamp applied as far as possible away from the ligature. A clamp is then applied to the distal end of the donor's vein, the vessel is stripped of blood toward the heart and ligated proximally. Each vessel is in turn cut squarely across near its ligature, caught up at three equidistant points by mosquito forceps, and irrigated with warm salt solution. The cannula end is introduced into each vein and tied in position so that one cannula is continuous with the recipient's vein and the other with the vein of the donor. The clamp on the donor's vein is released and a syringeful of blood is carefully aspirated. The clamp is then replaced and the one on the recipient's vein removed. The blood is very slowly injected into the recipient and the clamp reapplied. This procedure is then repeated until sufficient blood has been transfused. The danger of fat embolism from the petrolatum used is considered negligible. The advantages claimed are: the definite control of the amount of blood

and the rate of flow, simplicity of technique and saving of time, assurance of success in the transfer of blood, and lessened danger of infection to the donor.

Diphtheria and Public Health.—J. P. Simonds concludes that the influence of school attendance on the incidence of diphtheria is shown (a) by the very large percentage of cases that occur in children within the school age, and (b) by the higher monthly average of positive cultures received during the school months as compared with the vacation months. The chances of error in the clinical diagnosis of diphtheria are so numerous and the period of time during which virulent bacilli may remain in the throat after apparent recovery is so variable that a physician is never justified in quarantining or releasing a diphtheria patient without a bacteriological examination, if such is obtainable.

Pyelitis of Pregnancy.—A. E. Chace enumerates the predisposing and exciting causes. The predisposing causes are given as follows: 1. Pressure on one or both ureters by the gravid uterus. 2. Infection of the urinary tract. 3. Complication is often alleged as a possible cause, *Bacillus coli* being here the most frequent exciting cause. 4. Infectious diseases. 5. Traumatism, said by MacFarlane to be more frequent than is generally supposed. 6. Physical conditions inducing lowered vitality. 7. It appears to be slightly more prevalent in primiparæ. 8. From the fifth to the eighth month is the usual time of onset. The exciting causes are: (1) gonorrheal infection; (2) pyogenic micrococcus infection; (3) *Bacillus coli* infection; (4) tuberculosis. In the case of the latter, suspicion may arise of its pre-existence before the pregnancy. Gonorrheal and micrococcal infections are more probable, but the literature does not give data for percentage statement. The author's findings seem to indicate that the *Bacillus coli* infection is most frequent. The diagnosis is that of a pyelitis developing for the first time during pregnancy and usually disappearing before or during the puerperium. The onset may be insidious or stormy, and the course depends on the exciting cause and treatment. In forty cases collected by the author, premature labor occurred four times, was induced once, nephrotomy was performed ante partum once, and four times post partum. The rational treatment supported by experience is: (1) absolute rest in bed; (2) fluid, preferably milk, diet; (3) mild catharsis; (4) hexamethylenamin, 0.5 gm. every three hours day and night in a full glass of cold water—the frequency of dosage is lessened as symptoms improve; (5) posture to relieve the ureter on the affected side, if the infection be single; (6) interruption of pregnancy is seldom if ever necessary; (7) autogenous vaccine treatment is favored by Hicks, future experience may prove its value; (8) topical applications in the bladder or pelvis of the kidney of salts of silver or other like antiseptics seem to be of service in severe cases, but in average cases of coli infection hexamethylenamin will alone suffice. A typical case is reported, *Bacillus coli* being the apparent cause. The case was attended with severe itching and eruption, which disappeared after the cessation of pregnancy.

Obesity and Certain Changes of Metabolism. O. Rozenraad.
A Simple Serum Diagnosis for Tubercle; also a Method of Obtaining an Immunity Index. V. B. Nesfield.
The Clinical Aspects of "Juvenile General Paralysis," with an Account of a Case Treated with 606. J. Abraham.

Obesity and Certain Changes of Metabolism.—O. Rozenraad states that obesity and glycosuria are kindred diseases; about 50 per cent. of all obese persons suffer from glycosuria, though this seems to have little prognostic value. With glycosuria heredity is an important factor in its etiology; sometimes one finds that diabetes and obesity are combined with a neurasthenic disposition. Obese persons die young, a fact well known to the insurance companies, and they do not recover well from the effects of surgical operations. The presence of obesity itself produces during lifetime cardiac troubles and arteriosclerosis, also physical and mental inactivity. The primary cause of obesity lies in a misproportion between the energy taken in the food and the amount expended by the body. The remainder of the food, not burnt up and lost as heat and work, is stored up as fat. It is Oertel's merit to have pointed out to the profession how much benefit cardiac cases receive by a reduction of weight. In some cases the patients have entirely recovered from asthmatic troubles and emphysema; even cases of locomotor ataxia and kyphoscoliosis are reported by von Noorden to have markedly improved after reduction of weight. The difference formerly made between anemic and plethoric obesity has been given up; the distinction now made is whether the case is a case of endogenous or exogenous metabolism. As endogenous have to be considered all cases in which combustion is abnormally low, when dieting has no effect, and thyroid extract as a stimulant for the oxidizing process has to be resorted to. The results of the author's experiments tend to show 13 per cent. of liquid substance in the fat cells, but there is a slight difference if the fat is taken from the heart, the abdomen, or the kidneys. With the fat of the heart there seems to be a slight increase of the water. The low amount of water contained in fat cells gives one an explanation why it is practically of no difference whether the amount of liquids be reduced in the diet—with 13 per cent. of water contained in fat cells it is of no importance whether liquids are given or not—the fat cells do not take more fluid, and would not be influenced by a reduction of liquid given. There are relations between corpulency and secretions of the hypophysis. The extract of the hypophysis is able to reduce corpulency as well as the thyroid extract. In former days much importance was given to sexual obesity; the extirpation of the testes seemed to produce corpulency—the eunuchs of the Turkish harem were always quoted. Yet even complete withdrawal of the ovaries or testes may have no effect on the metabolic process. Common sense is the line upon which the diet has to be carried out. Every case has to be individually treated and the diet very carefully watched. It is, therefore, of importance that the carrying out of the diet be observed by the medical man, and not left to the will of the patient. A good surgeon knows when not to operate, a good physician knows when reduction of weight is no longer necessary, for the patient too often wishes to be reduced in weight in a very short time—a mistake that might soon be followed by general weakness due to muscular debility of the heart.

Serum Diagnosis of Tuberculosis.—V. B. Nesfield, with a view to discovering traces of immune substance in the serum of tuberculous patients, carried out a series of tests, taking as his basis the fact that the immune body combines with its specific bacterium or toxin, and that this bacterium-immune compound unites with complement. It is the principle employed by Wassermann for the diagnosis of syphilis. It is noted that this test is on the lines of Flemming's modification of the modified Wassermann reaction, with the difference that the relation of the immune body to the complement is standardized in place of the antigen. It would, no doubt, also give a means of estimating the degree of reaction in the Wassermann test for syphilis. Wassermann and Brück in 1906 failed to demonstrate this fixation test for tubercle; their procedure was different, and perhaps they failed to pay attention to the tonicity of the fluids employed.

Juvenile General Paralysis.—J. Abraham discerns in the history of juvenile general paralysis a curious re-

semblance to that of many other diseases once considered rare, but now generally recognized as of comparatively frequent occurrence. It is noted that either the condition is becoming more frequent or else is being more readily diagnosed. Probably both suppositions are correct, yet undoubtedly, although the alienist is now constantly on the lookout for such cases, the medical profession as a whole has not yet grasped either their importance or their frequency; and, considering their invariably fatal termination, sufficient stress has not been laid on the paramount importance of treating every child, of known syphilitic parents, giving a positive Wassermann, whether it shows signs of congenital syphilis or not, as carefully as if it were an adult with definite symptoms of the disease; for it is a peculiarity of juvenile general paralysis that many of these children show absolutely none of the stigmata of congenital lues, though nearly all give a positive Wassermann.

Hyperchlorhydria and Its Complications. W. Russell.
The Distribution of Appendicitis, with some Observations on its Relation to Diet. O. T. Williams.
A Contribution to the Clinical Study of Chronic Movable Kidney. P. Hicks.
The Use of Old Tuberculin Ointment in the Diagnosis and Treatment of Lupus Vulgaris. A. Verge
Cancer of the Breast. Amputation and After-treatment by Secondary X-Rays of Known Quality: A Suggestion. W. Mitchell.
A Note on Cleft Palate Operations. T. S. Kirk.
A Case of Dwarfism. A. A. Jubb.

Hyperchlorhydria and Its Complications.—W. Russell states that the symptoms of hyperchlorhydria not infrequently come on somewhat acutely, in strong, vigorous persons who have not suffered previously from digestive disturbance of any kind. The symptoms are burning pain at the cardiac orifice of the stomach, acid eructations, waterbrash, usually flatulence, and constipation. In other cases there is a sense of dragging or weariness, referred to the stomach, or a hunger-discomfort, coming on two hours or less after breakfast perhaps, and removed by taking a glass of milk, a drink of cold water or soda water, or a cup of tea. In other cases, and more commonly somewhat later in life, much gastric discomfort, or definite pain comes on from one or two hours after a meal; and this is associated with mental depression, and great difficulty, amounting in some instances to complete incapacity for mental or physical effort. The misery of the hyperchlorhydriac leads him to reduce and reduce his feeding in the hope of freeing himself from his depression, and he becomes thin and haggard in appearance. Sometimes he gets relief by vomiting, more commonly he does not vomit. He often gets relief by the eructation of some mouthfuls of very acrid stuff. His pain lasts for an hour or two, and if it lasts up to his next meal, the taking of it relieves him for some time, the duration of the relief depending upon the composition of the new meal. The complications are acute gastric or duodenal ulcer, pyloric spasm, chronic gastric ulcer, chronic duodenal ulcer, gastric dilatation, (a) of fundus, (b) ptosis of lower border (including other causes leading to the lower border being below the level of the pyloric outlet), and gastroptosis. The author concludes that if chronic gastric and duodenal ulcer are excluded, the question of operation hangs upon, first, the determination of the position of the inferior border of the stomach to the pyloric outlet; and, secondly, upon the prospect of being able to restore the sagged lower border.

The Distribution of Appendicitis.—O. T. Williams concludes that appendicitis has a markedly different incidence in various countries, and that this different incidence may be very largely a question of diet. Many theses have been advanced to explain this relationship to diet. Statistics show that where there is a large meat eating population there appendicitis is a common disease, whereas in those countries where little meat is eaten appendicitis is rare if not almost unknown. There is no doubt, according to most people, that apart from improved diagnosis appendicitis has greatly increased in the British Isles in the last few decades. Very little evidence has so far been advanced in any explanation of this. The greatest change in the diet of the people has undoubtedly been the marked increase in meat eating. With the amount of foreign meat and canned food the poorer classes even are now able to supply themselves in fair quantity with meat of varying kinds, more particularly mutton. The fat of meat, more particularly of mutton and beef, is characterized by the small amount of unsaturated fatty acid it contains. That the fat in the food determines the nature of the fat in the tissues is well known. From the clinical and chemical work quoted it would seem that this factor determines the nature of the soaps to be found in the wall of the intestinal tract (probably as a manifestation of their excretion), and where these soaps are the calcium soaps of saturated fatty acids there is usually some evidence of disease, either a mucous colitis or an intestinal lithiasis In appendicitis, with which these two conditions are clinically associated, there is the same occurrence of these calcium soaps in the wall or in the lumen. In the author's opinion there is some evidence to connect the nature of the fat in the food with the incidence of the disease Experiments which have been recorded show that the fats in the tissues are not neutral fats but complex phosphatides, the fatty acid radicles of which are largely unsaturated, and evidence is being obtained which would tend to show that these unsaturated fatty acid radicles are those which are used for the immediate use of the body, and it is possible that the calcium soaps are evidences of some excreting process of the intestinal tract for the purpose of eliminating either the calcium or saturated fatty acid radicle.

Chronic Movable Kidney.—P. Hicks stated that most chronic movable kidneys are probably the seat of some degree of hydronephrosis, not acute enough in its incidence or condition to cause pain. It is a fact that in acute cases, where hydronephrosis is believed to exist, it is difficult to estimate its extent by palpation through the abdominal walls, operation often revealing a much more extensive collection of fluid than had been suspected. The inevitable kinking of the ureter must always, or almost always, produce retention of urine in the kidney pelvis; and the degree of pressure upon renal substance of this retained urine must depend directly upon the degree of ureteric obstruction. When the displacement is associated with the usual obvious symptoms—pain, dyspepsia, etc.—measures should be taken to support the kidney in its proper position. Here the sequence of cause and effect are plain, and no dispute can arise. But there are certain cases of marked neurasthenic and minor mental symptoms in which the discovery and support of movable kidneys have been followed by most remarkable improvement. The symptoms of chronic movable kidney are pain, dyspepsia, nausea and vomiting, urinary symptoms, palpitation, tachycardia, loss of flesh, and pelvic symptoms. The author submits the following propositions: 1. That no neurasthenic symptoms in any young person of either sex, or in an early stage, should be accepted as neurotic in origin without the fullest investigation and examination, and that, if necessary, such examination should be repeated over and over again before the final condemnation is uttered. 2. That no case of movable kidney discovered in any such patient should be allowed to go untreated, and this even and especially so in cases where no abdominal symptoms are present. 3. That in all cases of early mental disturbance accompanied by depression, unreasonable weeping, loss of memory, vagueness, restlessness, suicidal tendencies, and especially where

these symptoms are accompanied by any sort of pains in the head, the same methods of investigation and, where necessary, of treatment should be used.

Old Tuberculin Ointment in Lupus.—A. Verge describes his method of treating lupus as follows: The part being carefully cleansed, and after the application of a starch poultice to soften and remove any crusts which may be present, an ointment consisting of a 5 per cent. solution of Koch's Old Tuberculin in a basis of paraffin molle, is well rubbed in from one to two minutes. A piece of linen or lint, freely smeared with the ointment, is then applied, and allowed to remain for 24 hours. Where possible, a firm bandage is used, or fixation insured, by means of plaster, to prevent the ointment being spread over the surrounding skin and reaching undesirable positions. On removal of the application, varying degrees of hyperemia and swelling are seen in the actual lupus tissue, with a moderate amount of hyperemia, with reddish papules extending one or two inches into the surrounding healthy skin (Moro reaction). After cleaning the surface, similar applications are made for the next three or four days, the number being regulated by the pain experienced, in some cases considerable, and by the natural objection of the patient to the peculiar odor which arises in all cases. In 48 hours the swelling and hyperemia are very well marked. As one proceeds with the treatment the part becomes more and more inflamed and swollen, small vesicles appear over the situation of the lupus nodules, and these on rupturing leave small ulcers behind, showing that the nodules have been eroded. The appearance of the lesion now closely resembles that produced by the application of a salicylic acid plaster. This is the desired effect, and the treatment is now suspended, and the inflammation allowed to subside under some soothing application. Healing is usually complete within 10 days, when the beneficial result may be observed.

X-Ray in Cancer of the Breast.—W. Mitchell quotes Barkla who states that elements of high atomic weight transform x-rays which strike them into a secondary radiation much more absorbable and more intensely ionizing than the incident rays. These secondary radiations are, he states, of two sorts: x radiation, which depends for its quality upon the characteristics of the particular element emitting it, and a β radiation similar to the radiation of radioactive substances. He further states that the physiological effect upon the tissues, normal or pathological, depends upon the amount of the ionization of the tissues in question. Further, he states that if a tissue be injected with a heavy substance like bismuth carbonate, and then irradiated with an x-ray tube in the ordinary way, this substance (bismuth carbonate) will give off x-rays of a constant quality, and that these secondary rays will produce a much greater and more intense ionization of the tissue, and hence greater physiological effect, than would have been produced by the irradiation had the bismuth carbonate not been injected. This suggested to the author a procedure that might be useful to surgeons and radiologists alike—namely, after amputation of the breast, to impregnate the wound, before closing it, with sterilized carbonate of bismuth. This, if done not too profusely, would not in any way interfere with the healing of the wound. The bismuth then would become incorporated with the tissues at the very points where recurrence would be most likely, namely, along the lines of excision, and when healed, or even before, one would have all ready prepared the very condition which is the ideal one for further treatment by irradiation.

Cleft Palate Operations.—T. F. Kirk claims for the use of a continuous suture that it gets rid of two of the causes of failure of union in cleft palate operations, namely, imperfect apposition of the flap edges and necrosis of the flap edges from stitch pressure, and that it considerably shortens the operation, thus materially diminishing its risk.

A Case of Dwarfism.—A. A. Jubb reports a case of this condition simulating achondroplasia. The conjunction of rickets and a mild degree of hydrocephalus suggested that congenital syphilis had been the cause of the infantilism.

Berliner klinische Wochenschrift.

December 26, 1910.

Splenomegaly, Hydronephrosis, Cancer of Ureter.—Israel discusses the case of an aged woman who presented all these lesions simultaneously. The problem referred to the questions of accidental incidence and of cause and effect. Primary cancer of the female ureter is one of the rarest of accidents, the author having seen but the case in question. The massive infiltration of the ureter by a cancer of the villous type was sufficient to cause the hydronephrosis. The coincidence of this lesion with Banti's disease is doubtless purely accidental. The spleen was enlarged, and in consequence there were enlargement of the liver and jaundice. The case would doubtless have proceeded to cirrhosis of the liver in due time. During life the case suggested a combination of a splenic and renal tumor. At autopsy there seemed to be no definite relation between the two. Such cases suggest that the complication of diseases which carries off elderly people may in reality represent entirely different processes, not merely links in a chain, the occurrence of several together depending only upon the fact that such patients are receptive to all causes of disease.

Relationship between the Status Lymphaticus and Addison's Disease.—The author (von Werdt) discusses a class of cases by no means new in clinics in which we find general lymphatic enlargement, often with tuberculous foci, persistent thymus, enlarged suprarenal bodies, and, in some cases, lesions of the heart. In some cases lesions of the suprarenal capsule and contributory nerves add the picture of Addison's disease. The case described by the author shows nothing new. Autopsy revealed Addison's disease, chronic tuberculosis of both suprarenals, and enlargement of most of the lymph nodules, with dilatation of the heart, and persistent thymus. The case was in fact one of pronounced status lymphaticus. But minute anatomy throws but little light on the nature of the process, which remains much as in a previous decade. While debating the nature of the previous case, a second one came in evidence—one of status lymphaticus and Addison's disease. Patient was a woman, aged 32, with typical Addison pigmentation, myasthenia, etc. Autopsy showed a caseation of both suprarenals, with tuberculosis of the right tube and liver and general enlargement of all the lymph nodes, tonsillar structures, Peyer's glands, etc. The heart showed evidences of myocarditis. The sympathetic and solar plexus showed an abeyance of normal features, as did also the suprarenal bodies—all the autopsical findings together representing, as von Werdt notes, a distinct hypoplasia of the chromaffin system.

Metastatic Conjunctivitis.—Rusche discusses this subject from all points of view. Metastatic ophthalmoblennorrhea may originate from urethroblennorrhea, and is usually associated with arthroblennorrhea, and not rarely with metastatic iritis. In all secondary infections the subject of immediate propagation must become involved. A true metastasis to the eye is characterized by absence of the gonococcus in the conjunctival secretion. The diagnosis of a true metastasis from the urethra to the eye is therefore, Rusche says, made evident by the presence of gonococcic joint disease, secondary iritis, and corneal disease.

Münchener medizinische Wochenschrift,

December 27, 1910.

Treatment of Pregnancy Toxicoses with the Serum of Pregnant Women.—Mayer and Lindner have considered this subject jointly, the former taking the theoretical side. He gives an excellent account of our present knowledge and regards all severe affections of pregnant women, such as can not be shown to be purely coincidental, as due to one or more intoxications. In addition to hyperemesis, acute yellow atrophy and eclampsia, he emphasizes the necessity of regarding herpes gestationis as a member of the same group. Former writers have given but little space to this dermatosis as a possible manifestation of pregnancy toxicosis. Mayer looks upon it as really a pemphigus of fatal nature. In giving an explanation of the incidence of all these toxicoses, he states that they must involve the failure of the production of those antibodies which are normally found during pregnancy. In the case of herpes gestationis described, an opportunity for the injection of a pregnancy serum was readily available. The result, as described by Lindner, was the more striking, because universal skin lesions are the more studied. Two photographs show the disease, so frequently fatal in outcome, and the clearing up of the skin after use of the serum. The author styles the result as most striking. It is not often that a disease reputed to be uniformly fatal (in which recoveries are usually ascribed to error in diagnosis) may be seen to improve stage by stage under the naked eye. Such a result will necessarily be utilized in hyperemesis, acute atrophy of the liver, and eclampsia. In this case 10 c.c. human serum were injected in order to determine whether intolerance was present. The result being as hoped for, 10 c.c. were injected three days later from a second pregnant woman, followed in turn by 20 c.c. from a third pregnant woman. Such a method should not be difficult of execution in maternities.

Flexner Dysentery Transmitted in a Hospital by the Use of Eating and Drinking Vessels.—Bussow describes a small epidemic of dysentery in the isolation ward of a hospital. It was at first thought that the epidemic had originated from the admission of a latent case of the disease which had not been recognized. Later it was found that the cook and nurse, who had previously served certain dysentery patients, had been affected with severe diarrhea, but without general symptoms. They were at once isolated and Flexner's bacillus recovered from the stools of the cook. The nurse could be excluded as a carrier. The interest therefore centered about the cook, who used the patients' cooking and eating utensils, and those vessels used in isolation. It must be remembered that at that time no diagnosis of dysentery had been made. The cook is ordinarily present in the chain of infection. But in institutions in which dysentery is known to flourish the cook is always cut out of the infection circuit. Cases like this must be based on the supposition that the Flexner bacillus is prone to be transmitted by the food, as in the case of typhoid, and that the cook may become a bacillus carrier.

Local Action of 606.—Martins sums up this subject as follows: Naturally he refers to subcutaneous and intramuscular injections. Regardless of the dose, kind of solution, etc., we find extensive necrosis. All tissues are involved alike (connective tissue, fat, muscle, vessels, and nerves). The necrosis of the nerves gives rise to neuritic phenomena, and in certain cases to disturbances of the bladder. Necrosis in the vascular walls may cause thrombotic phenomena. The expelled necrotic tissues (skin and subcutaneous tissue) may contain arsenic in abundance. Under certain circumstances poisonous arsenical derivatives may be absorbed.

Deutsche medizinische Wochenschrift,

December 29, 1910.

Survival for Four Weeks after a Shot Through the Aorta.—Momm describes very briefly a case of pistol wound in which the bullet passed through the liver and aorta. The victim was a young married man, shot by his newly wedded spouse. The diagnosis of fatal internal hemorrhage led to a prompt laparotomy, with a rapid emergency tamponade. This was removed eight days later. There was no further hemorrhage, but five days later an aneurysm of the external iliac came in evidence. The connection with the pistol wound was not apparent, but an attempt was made to tie the affected vessel, especially as gangrene of the foot had appeared. It was intended to ligate the artery at Poupart's ligament, but incision showed the bullet between the femoral artery and vein, the latter being thrombosed. Patient died of the resulting gangrene, twenty-seven days after the injury. Autopsy showed that the bullet had penetrated to liver and lacerated the aorta about 12:5 cm. above its bifurcation. Some attempt at repair seems to have ensued, but the left common iliac was plugged, and this clot was eventually responsible for the patient's death. The ball had never left the artery, but had been carried down to the femoral, from which it worked its way out. Death actually occurred from sepsis The case is believed to have been unique.

Transfusion of Fresh, Defibrinated Blood.—Moldovan has taken up this old subject without reference to arm-to-arm transfusion of living blood. He does not even mention Crile's monograph on transfusion. His work has been done on animals, and he finds that the intravenous transfusion of defibrinated blood causes immediately fatal anaphylaxis This action does not differ in character from those obtained with the serum of defibrinated blood, on the one hand, or that of fresh erythrocytes. The element of coagulation in these bloods is very brief and unstable. The author concludes that it is an inimical process. It is strange that he should not even comment on the works of English and American writers.

On the Coloring Matter of the Living Substance of the Red Blood Corpuscles.—Hertz calls attention to the fact that the colorable granulations of living blood-vessels have nothing to do with the subject of basophile punctations. It is substantially identical with polychromatophilia. These as colorable cells are very common in anemia, and with conditions like blood-poisoning represent a regeneration of erythrocytes. We do not yet know whether degeneration or regeneration is implied by basophile punctation. It will be recalled that the first description of the tinctorial qualities of the granular matter of the erythrocytes in hemolytic icterus lead to the belief that such qualities were pathognomonic for the condition. We have since learned that they may occur in a variety of affections.

Hernia of the Intestinal Wall.—Prof. Riedel gives a brief clinical lecture on this subject. He concludes that it is much more common than has been believed. The affection may at times be confounded with iliac and femoral hernia, but a little incarceration causes no pain. Such a leasion is naturally readily overlooked. To replace such a hernia is contraindicated. As soon as diagnosis is made we should operate at once. Cases in which the opportunity for early operation has been lost may give much trouble.

Cause of the Cammidge Reaction.—L. Gumpert and R. Bernier find that this reaction is present in the normal urine to a slight degree and attribute its production to the pressure of paired glycuronic acids.—*Comptes Rendus Bebdommedaires des Séances de la Société de Biologie.*

Book Reviews.

Courtship Under Contract. The Science of Selection. A Tale of Woman's Emancipation. By James Henry Lovell Eager. 450 pages. New York: The Health-Culture Company, 1910.

This book is evidently intended to be a study of eugenics told in the form of a love story. The story is extremely improbable and not interesting or convincing.

History of Medicine. By Dr. Max Neuburger, Professor of Medical History in the Imperial University of Vienna. Translated by Ernest Playfair, M.B., M.R.C.P. In two volumes. Vol. I. London: Henry Frowde, Oxford University Press; Hodder and Stoughton, Warwick Square, E. C., 1910.

It is unfortunately true that the subject of medical history has in the past received much less attention from writers of the English speaking race than has been the case on the Continent. Of late interest in this field has been growing and both in this country and in England numerous important biographical and other contributions have been made, but still we can as yet show no such authorities as Gurlt, Hyrtl, Haeser, Puschmann, Pagel, Neuburger, and many others. The appearance of an English edition of Neuburger's very excellent work is accordingly a matter for considerable congratulation; especially as the translation has been most beautifully done by Ernest Playfair. The value of such a work as this depends in no small measure on its literary form, and the success of the translater in providing so polished a rendering of the German original is worthy of especial comment. The volume opens with a short introduction by Osler in that delightful writer's best vein, and a chapter on primitive medicine. The body of the work is divided into four sections, dealing respectively with the medicine of the East, medicine in classic antiquity, medicine in the decline of antiquity, and medicine in the middle ages, thus leaving for the second volume what may be termed modern medicine. A more or less continuous narrative is given in large type, while about one-quarter of the letter press is in small type, and contains more detailed descriptions, citations from authorities, etc. While, of course, not so comprehensive a work as the monumental *Handbuch der Geschichte der Medizin* begun by Puschmann and completed by Neuburger and Pagel, the present is perhaps more suitable for the purpose of the general reader and student since it permits a satisfactory comprehension of the evolution of medical thought and at the same time affords enough detailed information concerning individuals to make it useful for purposes of reference. The publishers should be complimented as well as the author and translator, for they have issued the book in most attractive form; paper, print, and binding are far above the average of what is seen in medical works.

Vorlesungen über Harnkrankheiten für Ärzte und Studierende. Von Dr. C. Posner, A. O. Professor an der Kgl. Friedrich Wilhelms-Universität zu Berlin. Berlin: Verlag von August Hirschwald, 1911.

This is a scholarly and comprehensive review of genito-urinary diseases modestly presented to practitioners and students. The first section, of one hundred pages, is devoted to general etiology, diagnosis, and treatment. The directions for examination of the patient are written with painstaking detail, and this is probably the finest chapter in literature on that topic. Under instrumental diagnosis full attention is accorded the various instruments, individual preference being expressed for the Wossidlo, Goldschmidt, and Valentine urethroscopes and the Nitze cystoscope. A calm and impartial opinion is given of the limitations of urinary segregators. The different genitourinary operations are mentioned and technique described as fully as possible in a work of this character. Under gonorrhea the author speaks of general and individual prophylaxis and favors the latter, believing that thereby many individuals have been saved from infection. Mention is made and the treatment outlined of rectal and buccal gonorrhea, whose very existence has been denied by other competent observers. In the treatment of acute gonorrhea injections of organic silver salts and astringents are advised in preference to irrigations. All that is written on chronic gonorrhea, its complications and sequelæ coincides with the dicta of the German school founded by Oberlaender and Kollman. The chapters on tuberculosis, calculi, tumors, and nervous disorders of the tract are conventional, and present no new theories or principles. The book ends with fifteen pages on disturbances of the sexual function. This dignified work is befitting the author's deep knowledge and long experience in his specialty.

A Manual of Physiology with Practical Exercises. By G. N. Stewart, M.A., D.Sc., M.D. Edin., D.P.H. Camb., Professor of Experimental Medicine in Western Reserve University, Cleveland; formerly Professor of Physiology in the University of Chicago; Professor of Physiology in the Western Reserve University; George Henry Lewes Student; Examiner in Physiology in the University of Aberdeen; Senior Demonstrator of Physiology in the Owens College, Victoria University, etc. With Colored Plates and 450 other illustrations. Sixth edition. New York, William Wood & Co., 1910.

The distinguishing thing in this Physiology is the manner of introducting practical exercises along with the formal exposition of the subjects. It is the sixth edition in fourteen years, the previous one having appeared in 1905. It is especially designed for laboratory workers, but both students and teachers will find it well adapted to their needs, concise in compass, and clear in statement. Each of the fourteen chapters has a full complement of experiments, making the book a complete manual. Both the physics and chemistry of physiology are treated well. We can wish we knew more of the remote chemistry of the living organism, especially in the face of disease, but so far as knowledge up to date goes it may be found here. On the interesting question, why the alimentary canal does not digest itself, the recent work of Weinland is quoted, who found in the intestinal parasites antiferments which resisted the action of both pepsin and trypsin. While not proved, the suggestion that the alimentary mucous membranes have such specific powers, and not merely that general resistance to destruction that all living tissues have, offers a good field for investigation. One matter of satisfaction, important to the reader, is the size and clearness of the type, the admirable quality of the paper, without a glary sheen, and the spring binding.

A Manual of Diseases of the Nose, Throat, and Ear. By E. Baldwin Gleason, M.D., Clinical Professor of Otology at the Medico-Chirurgical College, Philadelphia. Second Revised Edition. 12mo, of 563 pages, profusely illustrated. Philadelphia and London: W. B. Saunders Company, 1910.

This edition of the author's well-known manual has been reduced in bulk about sixty pages, and many sections have been practically rewritten. New material has been added on the topics of membranous rhinitis, nasal mycosis, Ludwig's angina, Vincent's angina, leprosy as affecting the upper air tract, intracranial complications of ear diseases, and the climatology of diseases of the upper air passages. The formulary at the end of the book has been thoroughly revised. The book is of convenient size, and well worthy of its claims.

Biology, General and Medical. By Joseph McFarland, M.D., Professor of Pathology and Bacteriology, Medico-Chirurgical College of Philadelphia; Fellow of the College of Physicians of Philadelphia. With 160 illustrations. Philadelphia and London: W. B. Saunders Company, 1910.

Medical science is a branch of biology, and for this reason a book that presents the principles of general biology with special reference to their bearing upon medicine may be of value to the prospective or actual medical student as well as to the physician. He who has already studied biology in his college course will find in this book a good deal that he already knows. But there is much besides that is presented from a new viewpoint, whose interest will grow as the student progresses in his medical course. Of peculiar interest are the problems of blood relationship, infection, immunity, parasitism, inheritance, mutilation, regeneration, grafting, and senescence. These subjects are presented fully in their medical bearing. The phenomena of specific precipitation and hemolysis are described as tests of blood relationship. The chapter on grafting presents the results of recent experiments in the transplantation of tissues and organs. The Mendelian law of heredity is clearly explained. These are instances of the effort of the author to make this book strictly a medical biology, and in this he has succeeded.

The Essentials of Histology: Descriptive and Practical. For the Use of Students. By E. A. Schäfer, M.D., Sc.D., LL.D., F.R.S., Professor of Physiology in the University of Edinburgh, formerly Jodrell Professor of Physiology in University College, London. Eighth Edition. Philadelphia and New York: Lea & Febiger, 1910.

It is twenty-five years since the first edition of this widely known book appeared. The present edition, enlarged chiefly by the additional illustrations, represents what seasoned experience has shown to be essential for the student of medicine. The book is divided into fifty lessons, supposed to occupy from one to three hours.

A Textbook of Pharmacology and Therapeutics; or the Action of Drugs in Health and Disease. By Arthur R. Cushny, M.A., M.D., F.R.S., Professor of Pharmacology in the University of London, Examiner in the Universities of London, Manchester, Oxford, and Leeds, formerly Professor of Materia Medica and Therapeutics in the University of Michigan. Fifth Edition, thoroughly revised; illustrated with sixty-one engravings. Philadelphia and New York: Lea & Febiger, 1910.

This book fills a niche peculiarly its own; it is chiefly concerned in the action of drugs, and it gives the physiological bearings of most of the drugs in use. The author's object has been to bridge over the gap which exists between the phenomena occurring in the normal organism and those which are elicited in the therapeutic use of drugs, and to show how far the clinical effects of remedies may be explained by their action on the normal body, and how these may in turn be correlated with physiological phenomena. For the general practitioner this is not the most useful work on therapeutics, but as an adjunct to any good work on therapeutics it is absolutely unrivaled. Not the least valuable part of the book is the bibliography, which is unusually well selected.

A System of Medicine. By Many Writers. Edited by Sir Clifford Allbutt, K.C.B., M.A., M.D., LL.D., Dsc., F.R.C.P., F.R.S., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Cains College, and Humphrey Davy Rolleston, M.A., M.D., F.R.C.P., Senior Physician St. George's Hospital; Physician to the Victoria Hospital for Children; Sometime Fellow of St. John's College, Cambridge Vol. VII. Diseases of the Muscles and Nerves, etc. London: Macmillan & Co., Ltd. New York: The Macmillan Company, 1910.

Volume VII of this well known series of monographs by eminent members of the English speaking medical profession differs somewhat in arrangement from that of the original edition. With the previous volume the purely medical part of the system was furnished, and the present volume deals with the diseases of muscles, the trophoneuroses, the diseases of nerves of the vertebral column and of the spinal cord. The section on diseases of the muscles has been considerably enlarged, while additional articles have been added on certain obscure conditions. The section on diseases of the nervous system has been to a large extent rewritten and reinforced by new articles. In fact, the entire volume has been brought up to date, a necessary undertaking in view of the great advance of neurology in recent years. The result may be said to be entirely satisfactory. Of the contributions which may be singled out for special comment is Sir William Gowers' paper on medical ophthalmology, which is included in the section on nervous diseases. Sir Victor Horsley, than whom no one is better qualified to pass an authoritative opinion, writes on the diseases of the vertebral column and compression paraplegia. One of the most interesting and instructive papers is that on caisson disease, by Dr. Leonard Hill, who refers to the investigations made by and preventive measures recommended by the late Dr. Andrew Smith of New York. Perhaps, however, the most valuable portion of the volume is the section which treats of the diseases of the spinal cord. Under this classification comes acute poliomyelitis, which is most fittingly discussed by Dr. M. Allen Starr. On the subject of acute poliomyelitis American physicians have the right, by reason of wide experience and careful investigation, to speak with authority, and Dr. Starr well represents the most recent knowledge of this obscure disease. One of the most striking chapters of the book, from the standpoint of literary merit, knowledge, and quality of the illustrations, is by Dr. Frederick W. Mott, entitled An Introduction to Neuropathology. Herpes zoster, which was formerly included among the skin affections, in the present volume is presented as a nerve disease. The article thereon is written by Dr. Henry Head, who gives a remarkably interesting and exhaustive description illustrated by numerous diagrams of this fairly common complaint. The hypercritical might find some fault with the arrangement of the volume, but little but praise can be given to the quality of the subject matter. The papers, while in line with modern progress in medicine, are, at the same time, excellently and judiciously conservative, and for the most part are distinguished by high literary merit. The illustrations are numerous and well fulfill their object. The volume is a veritable mine of valuable information in regard to nervous diseases and can be recommended as a most useful book of reference for the active practitioner. It reflects credit both on the editors and the contributors.

Urinary Surgery. A Review. By Frank Kidd, M.B., B.C. (Cantab.), F.R.C.S., Assistant Surgeon to the London Hospital. New York, Bombay, and Calcutta: Longmans, Green & Co., 1910.

The author describes his work as "an attempt to review for the use of the practitioner the progress of urinary surgery during the last decade." He divides his subject into five sections: Diseases of the Kidney, Ureter, Bladder, Prostate, and Urethra. The first two chapters, on "Routine Examination of a Urological Case" and "Development of the Kidney and Ureter," form a good foundation for the succeeding text. The section on diseases of the bladder includes a short chapter on Bilharzia Hæmatobia, a disease assuming more importance in England since the English occupation of Egypt and South Africa. Indications for various operations are fully and carefully considered, while the sections on operative treatment are more briefly sketched at the expense of detailed descriptions of technique. The paragraphs on bacteriological findings and their interpretation are conservative in tone and free from unnecessary quotations. The chapters on nephritis, pyelitis, tuberculosis of the kidney and ureter, and primary new growths of the kidney deserve especial praise, since they contain in condensed form all the latest knowledge in these fields. Earnest appeals are made to the practitioner not to overlook nor minimize mild transient hematuria or pyuria, which may be the precursory signs of grave diseases. The book ends with a short appendix on the origin of primary renal calculi. The literary style is clear and direct as that of a teacher, making less evident the paucity of illustrations.

Manuel pratique de la Lithotritie. Par F. Cathelin, Chirurgien en chef de l'Hopital d'Urologie, Ancien chef de clinique et Lauréat de la Faculté de Médecine de Paris, service du Professeur Guyon. Avec 145 figures dans le texte. Paris: Vigot Frères, 1911.

This timely work is the fourth volume of Cathelin's complete treatise on urinary surgery. The subject is discussed in the following sequence: a historic résumé of lithotrity, indications for the operation, description of the armamentarium, operative technique, and postoperative treatment. One short chapter is given to defense of the operation, in which he most correctly argues that "if an operation which has lived almost a century is not good, it is high time that it should pass into oblivion." Then follows a critical comparison between lithotrity and cystotomy and the statistics of Civiale, Bigelow, Thomson, Guyon, and his own. Of his sixty-three cases five died, one each from pulmonary congestion, embolism, rupture of the bladder, periurethral and perineal abscess, and intestinal atony with vomiting. The section on operative technique is fully detailed, including directions for the preparation of the patient and instruments, together with a description of the various maneuvers employed in atypical cases. He concludes: "Lithotrity, the ideal procedure for the extraction of a vesical calculus, constitutes at one and the same time an intervention, elegant, simple, and sure, three characteristics which justify an operation and are the gauge of its existence." The book is thorough, well illustrated, and written in true Gallic brilliance.

History of Chemistry. By Sir Edward Thorpe, C.B., LL.D., F.R.S., etc. Volume II; from 1850 to 1910. With illustrations. New York and London: G. P. Putnam's Sons, 1910.

This book gives a readable and accurate account of the history of chemistry from 1850 to 1910. The history is not a mere compilation, but is written by one who has a very extensive knowledge of the subject. The volume is well printed, is of handy size, and the inclusion of about a dozen portraits adds much to its value.

Psyche. A Concise and Easily Comprehensible Treatise on the Elements of Psychiatry and Psychology, for Students of Medicine and Law. By Dr. Max Talmey New York: The Medico-Legal Publishing Company, 1910

This book aims to present the rudiments of psychiatry for those who find it too laborious to wade through more extensive textbooks. For the lay reader and the student of law this brief treatment of the subject may be all that is necessary. But for the practitioner who would assume the responsibility of making a diagnosis or treating a case of insanity, dependence upon a concise volume such as this would be undesirable. The complex subject of psychology is covered in twenty-eight pages—a brevity that is certain to convey incorrect concepts. Moreover, one cannot agree entirely with the author's psychological views, particularly his hypothesis of the existence of a center for the affective tones, identical with the vasomotor center, and that pleasurable and painful feelings correspond to nutritive conditions of the brain.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 15, 1910.

THE PRESIDENT, DR. JOHN A. WYETH, IN THE CHAIR.

This meeting was held under the auspices of the Section on Obstetrics and Gynecology.

A Brief Memorial Address on the Late Dr. Robert Koch, Honorary Member of the Academy.—DR. JOHN A. WYETH delivered this address. (See page 95.)

Presentation of a Portrait of Dr. Robert Koch and a Brief Memorial Address.—DR. S. ADOLPHUS KNOPF made this presentation and address. (See page 96.)

The Clinical Peculiarities of Gonorrhea in Child-Bearing Women.—DR. BARTON COOKE HIRST of Philadelphia said that pregnancy, parturition, and the puerperium influenced the course of gonorrhea in women and gave peculiar characteristics which might be enumerated as follows: The possible effect of an antecedent infection upon conception; the consequences of coincident infection and impregnation; the virulent character of the inflammation in a pregnant woman; the comparative frequent occurrence of so-called gonorrheal rheumatism; the predisposition to streptococcic autoinfection directly after labor; the tendency to streptococcic necrosis of the pelvic organs in some mixed infections; and the frequent necessity of radical surgical treatment to save the patient. Gonorrhea was a cause of sterility. A salpingitis of specific origin necessarily prevented conception. In hospital practice it was a common experience to see cases of coincident infection and impregnation at the same coitus. Fatal results might follow or, at the best, a mutilating operation might be demanded. All had noticed the exaggeration of the symptoms of gonorrhea when the infection occurred after pregnancy was well advanced. Out of all the large number of gonorrheal pus tubes he had seen in his gynecological hospital and dispensary service in a period of over twenty years, he said he could not remember a single case in a non-pregnant woman of so-called gonorrheal rheumatism, *i.e.* subacute arthritis of one of the large joints; but in the University Maternity he had seen a comparatively large number of these cases in pregnant and puerperal women, usually with a clear history of gonorrhea, or with gonococci in the vagina or urethral discharge. If his experience was not exceptional, then the child-bearing process must be a potent predisposing factor in this disease. All had been impressed with the frequency of an autogenous streptococcic infection after labor in patients who had had gonorrhea for years, or who had acquired it during pregnancy. Occasionally an exceptional variety of pelvic infection after labor was observed in women whose husbands were known to have had gonorrhea. It could best be described as a fulminating suppurative salpingitis with pus dripping from the fimbriated extremities of the tubes which were not occluded. Gonorrhea was a serious complication of the child-bearing process. Women with gonorrhea should not conceive till the disease was cured. Pregnant women with gonorrhea should be treated with more energy than was usually required.

The Treatment of Gonorrhea in Women.—Dr. HERMAN J. BOLDT read this paper. He said that the treatment depended upon the stage of the disease. In the acute stage absolute rest and a light diet were demanded, especially at about the time of the menstrual period, since at this time exacerbations were most likely to occur, especially if there had been any physical exertion. None of the numerous remedies that had been recommended for the rapid cure of this disease could be relied upon. There was no abortive remedy. The best treatment during the acute stage consisted in boric acid douches and applications of stearate of zinc or zinc ointment. The chronic cases were very obstinate and required much patience in the treatment. The diagnosis of these cases was often a mere matter of chance. The urethra should be stroked and the droplet of pus expressed should be examined for the gonococci. It was comparatively seldom that one found vaginal gonorrhea in the adult because of the protection afforded by the pavement epithelium of the vagina. In cases of gonorrheal endometritis Dr. Boldt advised the thorough curetting of the uterus with the sharp curette. Such heroic measures should not, of course, be employed in the acute conditions or when the adnexa were affected, or when there was any evidence of pelvic inflammation. After the curette had been used the uterus should be packed with gauze saturated with, for example, a solution of a silver salt. The best time to institute such a treatment was shortly before the menstruar period, when the mucosa was more or less thickened. Cases of gonorrheal salpingitis should be treated most conservatively because a large proportion of them had pelviperitonitis. They should be kept in bed and given suppositories of codeine if the pain was severe. If sactosalpinges (distended Fallopian tubes) were present a cure could not be accomplished without surgical intervention. Whenever the cul-de-sac of Douglas was filled with exudate, the result of pelvic peritonitis, when the exudate could be readily evacuated by means of a vaginal section, this measure should always be employed.

Dr. JAMES CLIFTON EDGAR said that he felt very grateful and thankful to Dr. Hirst for what he had brought out; he did not mention any very acute affections as occurring during pregnancy, and Dr. Hirst's view regarding this was in accordance with his own. As a matter of fact, they did not see them; they did not have much harm from gonorrheal infections unless such infections took place at the time of conception. There were those who were so optimistic regarding the effect of a gonorrheal infection during pregnancy as to deny any morbidity or mortality; it did seem, however, that the enlarged uterus and the membranes, etc., offered more or less a protection to the uterine cavity against infection from the gonococcus. When the patient came to labor then a different clinical picture was presented. There might be a latent gonorrheal infection in, for instance, the endocervical glands, and, at the time of labor, this might be lightened up and cause trouble. Dr. Edgar was speaking entirely from the obstetrical standpoint. Another point of importance was that they often saw in cases of subacute or chronic gonorrheal infections a thickening of the cervix which gave trouble, dystocia, during labor; this hardening of the cervix was the result of a subacute or chronic condition and prolonged labor unnecessarily. It seemed to Dr. Edgar that the problem before them in the matter of gonorrhea during pregnancy and the lying-in state in its various clinical types was to know of some method of diagnosis, so that they might be forewarned before the puerperium. Dr. H. J. Schwartz and Dr. McNeil, working in the Laboratory of Clinical Pathology at Cornell, claimed that they had a method of determining from a blood examination the presence of gonococci. Their method was the development of a complement fixation test for the determination of a gonococcus antibody. The method was analogous to the Wassermann method. Dr. Schwartz and Dr. McNeil reported upon this method at the Section on Medicine, New York Academy of Medicine, October 18, 1910, and it was with their permission that he referred to the method.

Dr. Bailey, Dr. Edgar's associate at Bellevue, sent Dr. Schwartz and Dr. McNeil several specimens of blood from cases with fever in the post-partum period suspected of being due to the lighting up of old gonorrheal

infections, and they returned positive reports on certain cases where it seemed plausible to believe they were correct. One case of chronic post-partum sepsis where the only evidence of the trouble was a single inflamed knee joint gave a positive complement fixation test. Gram-negative cocci resembling gonococci were obtained by a smear from within the uterus. Blood counts were 13,000, 12,000, 8,000. They believed that this case was one of latent gonorrhea during pregnancy, and, starting up post partum, became a general blood infection. Believing the test might be of value in determining the presence of active gonorrheal conditions, antepartum, and thus become of value in the prevention of ophthalmia neonatorum in the newborn, they had had some 20 cases examined with 50 per cent. positive results. And in 60 gynecological cases Dr. Schwartz and Dr. McNeil claimed 25 per cent. of positive results. In positive obstetric cases they intended to cleanse the vagina thoroughly at full dilation, to hasten the second stage, and to irrigate the babies' eyes every six to eight hours with 20 per cent. argyrol solution during the first two or three days of the puerperium. This work would be followed and reported upon later. The results of their work appeared too good to be true, and the foregoing percentages too high; but when they recollected that upon such authority as Record and Erb gonorrhea was claimed to be present in the male from 45 to 80 per cent. the percentages in the female did not seem to be unbelievable.

Dr. Franklin A. Dorman said that many obscure cases of sterility seemed to be due to an antecedent gonorrhea and even when it was impossible to get a history of this condition. A large number of women who had had or who had gonorrhea would not conceive. If they did conceive, however, the disease process might remain latent, and without any warning at the birth of the infant danger from ophthalmia occurred. In some cases exacerbations with acute manifestations arose during the late period of pregnancy. Sometimes a woman would become infected with gonorrhea at the time she conceived, and this would be followed during her pregnancy with disastrous uterine consequences. It was very rare to find that these women with an acute gonorrhea, infected during pregnancy, had an infection advance beyond the cervix; but they did have an unusual exuberant growth of vulvar vegetations. At the Bellevue dispensary they often made a diagnosis of pregnancy when women presented themselves with these exuberant condylomata. As a rule, their diagnosis was correct. Many of these cases were seen at the City Hospital, and the growths appeared so very aggressive that active treatment was required to keep them within bounds. He recalled one case seen one or two years ago; in this individual the mass was so large that surgical interference was necessitated. These vegetations should be treated energetically and usually with some caustic such as carbolic acid. In his experience Dr. Dorman had not seen gonorrheal rheumatism more common during pregnancy than when the women were not pregnant. Dr. Boldt's suggestion regarding the treatment of the infected uterus seemed to many of them rather daring. He had seen some of these cases that had been thoroughly curetted lighting up infected tubes. One years ago Dr. Dorman had on opportunity to see a patient who gave the following history: Dr. Boldt had operated upon her in March, 1897, because of a bilateral salpingitis and peritonitis. The tubes were distended with pus, especially the left one. By means of the vaginal route the tubes were opened and drainage established. The abdominal wound was closed. The following year the abdomen was reopened and a tuboovarian abscess removed which ruptured during enucleation. An interesting fact in this case was that one year later this patient became pregnant and carried her child to term without any trouble. This was a striking example of the good result of conservative work upon the tubes.

Dr. Robert L. Dickinson said he rarely met with cases of gonorrheal rheumatism and had never seen an instance of it occurring during pregnancy. From Dr. Hirst's paper he got the impression that he believed puerperal gonorrheal salpingitis often flamed into peritonitis in such a way as to call for laparotomy and this through admixture with the streptococcus or staphylococcus. The very greatest difficulty was encountered in making a decision whether a laparotomy was justifiable or not. It should be remembered that the peritoneum had a very great ability to fight the enemy, and particularly the hereditary enemy of centuries, the gonococcus. He referred to two cases of extensive tubal peritonitis, cases between the seventh and the tenth week; over both hung, by an absorbable catgut thread, a knife of Damocles; but though severe and acute and with extensive involvement, the masses were practically out of the pelvis and slowly lessening. In the treatment of chronic gonorrhea in women there was one rebellious though minute trouble. Associated for many years with Dr. Skene, he had learned of his method of treatment of chronic infection of the urethral glands. Patchy chronic vulvitis, or chronic irritability of the bladder, or caruncle, or dyspareunia, were often present; until the causative trouble was located and treated properly there would be no cure of these affections. Dr. Skene took a tiny cautery wire tip and passed it into the gland and cut downward and outward to the vestibule or vagina with the hot wire. The slitting had been carried sometimes upward into the urethra. The first was often followed by an everted meatus which remained irritable and open to *Bacillus coli* infection. In the mild cases he injected pure carbolic acid; he used the little syringe used by dentists in cases of pyorrhea alveolaris, the Dunn syringe with the blunt gold needle. Dr. Dickinson looked over his office books and found that he had had 29 cases of chronic infection of the urethral glands, 19 of them gonorrheal and 3 tuberculous. A number of them would not yield to the carbolic acid treatment. The following he considered the best method of treatment: After the injection of eucaine-adrenalin solution the finest platinum cautery electrode, all metal, was passed to the bottom of the gland; the current was suddenly turned on very hot for an instant. There was no cutting or splitting outward toward either vagina or urethra. The number of treatments was usually two, at an interval of three weeks. Of thirteen thus treated, ten were completely cured. These were all long standing cases. If caruncle was due to this, no amount of snaring would do any good. One should get at the bottom of the cause.

Dr. George Gray Ward, Jr., said that gonorrhea in the female should be classified into two divisions, depending upon whether the infection was below the so-called danger zone (the internal os) or above it. Every case of acute gonorrhea situated below this danger zone was amenable to treatment because one could make direct applications of strong solutions of germicidal agents to those parts; but if the infection was above the danger zone, local treatment during the acute stage was absolutely contraindicated on account of the inevitable destructive inflammation of the appendages which would follow. Dr. Ward used a solution of nitrate of silver (30 grains to the ounce) when the disease was situated below the danger zone. The vulva was opened with a retractor to admit air, which dilated the vagina and obliterated the vaginal folds, and the solution was freely applied. The upper vagina was then packed with gauze impregnated with a 1-5,000 bichloride solution to prevent the disease traveling beyond the danger zone. Vaginal douching was absolutely prohibited on account of the danger of carrying infection to the region of the cervix. In acute or subacute cases, if the disease was

confined to the cervix or to the parts above, manipulation of the intrauterine cavity might produce permanent damage; if the general practitioner got the idea that cases of acute gonorrhea should be curetted there would be, in his opinion, great harm done. Such teaching was, therefore, dangerous unless very strongly qualified. Nature's barrier would be done away with, and the surface of the endometrium would be denuded and the gonococci would be rubbed deeply into the tissues, thus vaccinating the uterus with the infection. With regard to the use of vaccines, there were many who had different experiences from Dr. Boldt; in vulvovaginitis in children it seemed to Dr. Ward that one of their best weapons in fighting this disease was in the use of the vaccines. Reports given out by Dr. Hamilton seemed to make them worthy of trial. There appeared to be something in the use of vaccines in these cases, and certainly they seemed to promise more speedy cures in children. Dr. Ruth Vail, before the Chicago Medical Society, recently made a very valuable report of the use of vaccines in gonorrhea in adults, because the women under observation were inmates of the State Reformatory and were constantly under proper control. Dr. Vail's observations were of seventy cases of acute gonorrhea, which she divided into six series, as follows: (1) Those treated with vaccine alone; as much as 25,000,000 of stock vaccine were given once a week. (2) In this series, in addition to the stock vaccine injections, there was given local treatment, twice a week, of pure ichthyol. (3) In this series treatment with ichthyol alone was given. (4) In this series of cases a daily douche of normal saline solution was given. (5) In this series of cases antigonococcus serum was given. (6) In this series twice a week a 4 per cent. solution of silver nitrate solution was used; in cases with urethritis a 2 per cent. argyrol solution was given by injection. The conclusions reached were that the best results were obtained from the use of the vaccines and the serum; as to results they tallied about equally in regard to the disappearance of the cocci and discharge. The use of the silver nitrate gave no better results than any other treatment employed. The employment of the vaccines had certain advantages over the serum, such as (1) the volume of the dose was very small, one-quarter that of the serum, and, therefore, there was less reaction; (2) the intervals between the injections were longer; (3) the preparation of the vaccines was very much more simple; the use of the serum necessitated immunizing animals and was much more expensive. Dr. Dickinson had referred to chronic gonorrhea and especially the involvement of Skene's glands. As Dr. Ward was also an old pupil of Dr. Skene, he said he had long been interested in this phase of the disease. After cocainizing the parts, the ducts should be laid open with a small bistoury, such as the ophthalmologist used in opening the tear ducts; a piece of solid stick of lunar caustic was then fused with a flame on the tip of a fine wire probe so as to form a minute bead of silver nitrate on its end. This was then run up and down in the gutter made by the bistoury; the gland was thus destroyed after several such applications. A procedure of this kind, in his experience, was followed by the best of results.

Dr. John O. Polak, in answer to Dr. Hirst's query regarding the frequency of gonorrheal rheumatism occurring in the pregnant woman, said that in his experience the only cases he had encountered were in the pregnant woman. He could not recollect in eleven years' work at the Polhemus Clinic a single case of gonorrheal rheumatism that did not occur in one who was pregnant. The acuteness of a gonorrhea in women depended upon the receptivity of the particular patient. The gonococcus to his mind was similar to the streptococcus; its activity and virulence depended upon certain soils; in some soils the gonococcus was particularly active. The puerperal woman presented such fertile soil. Urethral lesions were more frequent in women just married or women with small introitus; while parous women were more apt to have an infection of the cervix. One point of particular interest to Dr. Polak was that if we left these acute gonorrheal cases alone, giving them rest, using cleanliness and postural drainage for the discharges, the acute stage would pass over faster than by any other form of treatment. The chronic and the subacute cases were often extended by too much local treatment in the office. This was a point that should be emphasized and was true not only in the chronic but in the subacute cases. In these women with a mixed infection, with a gonorrheal endocervicitis, one should not be too heroic in his treatment, because by being so he lowered the patient's resisting powers and spread the infection past the safety zone—namely, the cervix. Dr. Polak said he took issue with what Dr. Boldt said in teaching that cases of subacute or chronic gonorrhea should be curetted. What Dr. Boldt might do successfully others could not do. They all knew that the use of the curette in cases of chronic gonorrhea did frequently set up an active endometritis. These patients returned to them in after years with a chronic discharge. If it became necessary to remove the tubes he thought it better to do a hysterectomy, leaving the ovaries. What Dr. Boldt advised he thought was bad teaching for the general practitioner. One of Dr. Polak's assistants had been using a saturated solution of picric acid in these gonorrheal cases; the results of his work had not yet been published. In about one hundred cases of gonorrhea of the vagina, in which the gonococcus was found in pure culture, three to five treatments with picric acid entirely cleared the field of the gonococci. The method employed was very simple; the vagina was cleaned out thoroughly; a tubular speculum was introduced into the vagina, and one or two ounces of a solution of argyrol poured into the vagina. Then a wad of gauze soaked in a saturated solution of picric acid in glycerin was placed in the vagina. It was amazing to see the controls come back clear of the gonococci in from three to five treatments. Further reports on this will be forthcoming shortly in a monograph by Dr. Geis.

Dr. Henry Dawson Furniss said that his experience had been mostly with the chronic cases, and that in these the most frequent lesion found was in the urethra. Such patients usually gave a history of an acute attack, from which they recovered spontaneously. After a time there was likely to occur another attack, characterized by marked frequency in urination, not so troublesome at night as in the day; there was seldom any burning in these later attacks. Little if any pus was to be found in the urine. Upon examination there was to be found frequently some congestion of the trigonum and nearly always congestion or infiltration of the urethra. Any irritation seemed to cause the excretion of an actually greater amount of urine of low specific gravity. Dr. Furniss reported one instance where the patient after a nitrate of silver bladder irrigation passed twenty ounces of urine in forty minutes. The symptoms did not always bear a relation to the extent of the lesions; some patients with only slight congestion of the urethra being much troubled, while others with a urethritis, in which the mucosa was swollen, bled on gentle touch, yet they scarcely complained. Dr. Furniss said that there were other causes of urethritis than gonorrhea. Many cases were seen in women of the so-called rheumatic diathesis, and these responded well to treatment directed along this line. A few followed instrumentation. One should be on guard not to ascribe all post-operative cases to catheter infection. Some of these had acquired a gonorrheal infection after leaving the hospital from the husband, who had become infected during the wife's illness. He now had under his care a woman infected nineteen years ago in such a manner: after learning that he

had infected his wife, the husband committed suicide. Infection of Skene's glands did not occur as frequently as generally supposed. In these cases he had given up the cautery, as the destruction of tissue was too great. He now injected a solution of ¼ of 1 per cent. eucaine in a 1-8,000 adrenalin solution. This gave perfect anesthesia and complete hemostasis. To open the ducts he used a wire nasal speculum, a lachrymal probe, and a long slender bistoury. Congestion and infiltration of the urethral mucosa he believed to be much more frequent than the infection of Skene's glands. These cases of chronic urethritis he treated by thorough dilatation of the urethra with Hank's uterine dilators, and making topical applications of 1 per cent. to 7 per cent. nitrate of silver through the Kelly cystoscope with the patient in the knee-breast posture. He considered massage of the chronically inflamed urethra by the sounds of great benefit. He also employed hyoscyamus and alkaline diuretics.

Dr. A. Jacobi said that he saw more subacute and chronic than he did acute cases. He made applications to the endometrium by means of some little absorbent cotton wrapped around a whalebone probe of proper length. The difficulty in the treatment of such cases was that when silver nitrate, 2 to 5 per cent., was introduced into the uterus it would not spread; its effect was apt not to cover the whole mucous membrane. Therefore, it was often necessary to dilate the cervix. It was not necessary, however, to dilate the cervix in the usual run of practice Nitrate of silver cauterization was a local one only. Dr. Jacobi had been using for a long time tincture of iodine; this agent would spread over the entire inner surface of the uterus. This application could be made very easily and it was not necessary to dilate the cervix before its application. For this purpose he preferred to use Ferguson's cylindrical speculum.

Dr. Herman J. Boldt, closing the discussion, said that one should guard against any intervention during an acute process; in the presence of acute or chronic pelvic peritonitis, or any inflammatory condition of the adnexa caused by gonorrhea, one should not curette the uterus, as suggested. In the class of cases for which he had advised the treatment he had never found an instance resulting in any way unfavorably. With regard to the vaccine treatment, he said he had not had a sufficient number of cases upon which to pass judgment; so far, however, he had not had favorable results; negative results were obtained in both the young and the old. One of the most difficult conditions to cure, to which Dr. Dickinson had already referred, was the infection of the ducts of Skene. With regard to gonorrheal infection in the puerperal woman, frequently women conceived while they had chronic gonorrhea. During pregnancy they had, as a rule, no trouble whatever; but after delivery, in a large percentum of instances, there would be a rapid spread of the infection to the uterus, adnexa, and pelvic peritoneum.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 8, 1910.

Dr. Eli Long of New York and Dr. Charles A. Fife of Philadelphia in the Chair.

The Section on Pediatrics, New York Academy of Medicine, held a joint meeting with the Philadelphia Pediatric Society. The discussion of the papers was limited to members of the Philadelphia Pediatric Society. Following this meeting an informal smoker was given at the Yale Club.

Observations upon Three Hundred (300) Cases of Acute Meningitis in Infants and Young Children.—Dr. L. Emmet Holt presented this paper, which was read by Dr. John Howland. The observations included in this paper related to 300 cases of acute meningitis seen in the Babies' Hospital, in children for the most part under three years of age. Of this number 197 had been observed during the lumbar puncture period and were available for more careful analysis. Apart from epidemics of cerebrospinal meningitis, 70 per cent. of the cases of acute meningitis occurring in young children were tuberculous. During the last five years lumbar puncture had been performed about 1,000 times. Dr. Holt said there were two common misconceptions regarding tuberculous meningitis: the first was that it was a disease of long duration, often lasting two or three months. He had never seen tuberculous meningitis last over five weeks. Of the cases reported in this paper the average duration had been about two and a half weeks after the first definite symptoms of illness appeared. The second misconception was that tuberculous meningitis usually affected delicate infants, those suffering from malnutrition, often of the marasmus type. In his experience the vast majority of these patients, previous to their attack, were apparently in as good health as any he had seen. With regard to the seasonal prevalence, Dr. Holt presented an interesting chart which showed by months the time of admission of 218 cases. It was noted that the curve was at its lowest during the summer and early fall, that there was a slight rise in December and January, but a very sharp rise in the spring months, the highest point being touched in the month of April. The explanation of this variation was not altogether clear. With regard to the age incidence, there was a greater frequency of tuberculous meningitis in children from nine to twelve months; this might be due to the closer exposure of young infants to infected adults than occurred in children who were somewhat older. The following conclusions were offered: (1) Lumbar puncture had placed the diagnosis of meningitis upon a new basis. It should be employed in every suspected case. It was only in rare exceptions that to a skilled observer it gave uncertain results. (2) Nearly three-fourths of the cases of acute meningitis in young children were tuberculous, except when cerebrospinal meningitis was epidemic. (3) In tuberculous meningitis bacilli were always present in the cerebrospinal fluid; although difficult to find in the early stages, in the later stages a careful examination should disclose them. The von Pirquet test in most cases gave positive results. (4) In infants and very young children tuberculous meningitis occurred usually as an early manifestation of a general tuberculosis, and generally caused death before the lesions elsewhere were far enough advanced to give definite signs or symptoms. Pulmonary lesions were present in nearly all cases. (5) Tuberculous meningitis was of human origin. Altogether, the most frequent cause was exposure to adults with pulmonary tuberculosis. (6) The age incidence and the seasonal occurrence were points which were not yet fully explained. (7) Pneumococcus meningitis usually occurred in younger patients and was associated with pneumonia. Clinically it resembled meningococcus meningitis, but usually the course was shorter. It was almost invariably fatal. (8) Influenza meningitis was infrequent and also resembled the cerebrospinal form. It also was almost invariably fatal. (9) Streptococcus and staphylococcus meningitis were very rare in infancy and usually occurred in the newborn and were often associated with spina bifida. Under such circumstances they were always fatal. Meningitis from mastoid disease was seldom seen in young children. (10) Meningococcus meningitis was really the only variety in which at present there might be said to be any hope of recovery. The results in this variety of meningitis had been very greatly improved by the serum treatment.

The Constant Presence of Tubercle Bacilli in the Cerebrospinal Fluid of Tuberculous Meningitis: With

Observations upon the Cerebrospinal Fluid in Other Forms of Meningitis.—Dr. Josephine Hemenway said that a careful and systematic effort had been made at the Babies' Hospital to determine the presence of tubercle bacilli in the cerebrospinal fluid of cases of tuberculous meningitis; 138 patients had been admitted since March, 1906, but fluids for examination were obtained 137 times only. In all but two the tubercle bacilli were demonstrated in the cerebrospinal fluid. There was but little doubt that the bacilli were more numerous late in the disease, yet they were found in the first puncture in 117 cases; in the second, 13; and in the third, 4. On an average the first puncture was made about ten days before death. An examination of the cerebrospinal fluid was made in 22 cases of pneumococcus meningitis; the fluid in 20 could not be distinguished microscropically from the turbid fluids in other forms of meningitis. The cells were chiefly polymorphonuclear; the organisms were plentiful in the smears, and grew readily in cultures. The cerebrospinal fluid in four cases of influenza meningitis all showed great turbidity, the cells being practically all of the polymorphonuclear variety, and the influenza organisms were readily cultivated. In a series of 24 meningococcus cases, the fluid from 22 showed the usual turbidity and great numbers of polymorphonuclear cells, and the presence of the meningococcus in the smears and by culture. From a study of some histories Dr. Hemenway gave, the question arose whether there might not be a definite meningeal inflammatory lesion present with, at the same time, a clear cerebrospinal fluid from which no organism could be cultivated. In 10 cases of streptococcus meningitis the fluid from each showed great turbidity. There were many polymorphonuclear cells present, and streptococci were present in large numbers, and grew readily on the ordinary media. The globulin test of Noguchi appeared to be of great value in differentiating the normal from the abnormal fluids.

Influenza Meningitis and Its Experimental Production.—Dr. Martha Wollstein said that the employment of lumbar puncture as an aid in diagnosis had established the fact that the influenza bacillus was a not infrequent cause of seropurulent meningitis. Influenza meningitis appeared to be a very severe and highly fatal form of meningitis and to be exceeded in respect to its fatality only by the pneumococcus and tuberculous forms. Within the past year eight cases of influenzal meningitis had come under her observation; the influenza bacillus was isolated in every case from the fluid removed by lumbar puncture. All these cases terminated fatally. The influenza bacillus was a slender rod, somewhat varying in size, staining deeply at the poles, and being Gram-negative. Its invariable and most prominent characteristic was its hemophilic property, next to which pleomorphism was its most striking attribute. The most important of this series of animal experimentation were those which were conducted with monkeys. They succeeded in producing in two species (*Cercopithecus callithocus* and *Macacus rhesus*) infection of the meninges by injecting suspensions of the influenza bacillus into the subdural space by means of lumbar puncture. Thus an experimental form of influenza meningitis could be produced, which tended to run a rapidly fatal course, in this respect resembling the clinical disease occurring spontaneously in human beings. From all the facts given it would appear that the influenza bacilli from the cerebrospinal fluid from the cases of meningitis were identical with the bacilli commonly obtained from the respiratory tract and that the chief difference between the bacilli met with was one of virulence. The frequent finding of the influenza bacillus in cases of endocarditis, purulent arthritis, appendicitis, peritonitis, meningitis, and otitis, as well as their frequent occurrence in the bronchial and nasopharyngeal secretions, indicated that this organism, like the pneumococcus, was capable of causing inflammations of the serous and mucous membrane's anywhere in the body.

Dr. J. P. Crozer Griffith of Philadelphia said that when the subject of meningitis appeared on the program he felt glad to observe that reference to epidemic cerebrospinal meningitis had been to a large extent omitted. It would, indeed, have been carrying coals to Newcastle for members of the Philadelphia Pediatric Society to come to New York to discuss the latter subject, in view of the large epidemice of this disease from which New York had suffered in recent years. After hearing, however, the papers of the evening, the visitors were practically in much the same position. The topic had been treated so completely and in such detail that there remained really little to be said. All that he could do would be to give general impressions not based upon exact statistics. In looking over the records of the Children's Hospital of Philadelphia Dr. Griffith said he found during the last ten years that there had been admitted 239 cases of meningitis, of which number 121 were tuberculous. Although the diagnoses were necessarily primarily clinical, most of them had been confirmed by lumbar puncture and in many cases by autopsy also. There must necessarily be a certain proportion in which the diagnosis was not confirmed and was possibly incorrect, but on the whole the figures given might be taken, he thought, as fairly representative of the facts. So far as his practice outside the hospital was concerned, the great majority of the cases seen by Dr. Griffith were tuberculous, omitting from consideration those of the epidemic cerebrospinal type. Regarding the age at which tuberculous meningitis was most frequently seen, the majority, he believed, occurred during the first two years of life, although but few of them before the age of six months. In nearly all the cases of tuberculous meningitis the disease was clinically meningitis only. That was to say, there was no association of other symptoms. Perhaps the most frequent exceptions were seen, first, in older children suffering from tuberculous diseases of the bone, in which meningitis finally developed and caused a fatal ending; and, second, in infancy and very early childhood, in the cases of general tuberculosis, in which the meningitis was only one of the clinical manifestations and often the latest to show itself. At autopsy, of course, tuberculous meningitis was practically never found alone. Even when the chief manifestation it was probably secondary to a lesion somewhere else in the body, though this might be very small and possibly overlooked. With regard to the frequency of the tubercle bacilli in the cerebrospinal fluid, Dr. Griffith agreed with what had been stated. He thought they should be discoverable in the great majority of cases, although long and careful search might be required. As to the von Pirquet test, its absence was certainly a point against the existence of tuberculous meningitis except in the advanced cases where the reaction of the organism was no longer great enough to manifest itself. The presence of a cutaneous reaction, of course, would not prove that the case was one of tuberculous meningitis, but only that the tuberculous process existed somewhere in the body. This was a matter, however, so much written about that he did not dwell further upon it. During the last five years there had appeared in the wards of the Children's Hospital of Philadelphia 119 cases of meningitis; six of them were proven by lumbar puncture to be pneumococcic. In the matter of lumbar puncture, not only must a bacterial investigation be made but a careful cytoscopic study of the fluid as well. The common belief that tuberculous meningitis produced an increased number of lymphocytes in the field was, he thought, entirely correct, but was open to exceptions. Cases had been repeatedly reported in the medical literature where

the polymorphonuclear cells were proportionately greater, and Dr. Griffith had seen instances where the cytoscopic examination, taken by itself, would have suggested that the disease was of nontuberculous nature.

Dr. John Lovett Morse of Boston said that as the papers were being read he was reminded of a series of cases which he had recently seen in which the results obtained by means of lumbar puncture and the examination of the cerebrospinal fluid were disappointing in that they were confusing and did not afford a positive diagnosis. Dr. Morse had seen a number of cases of infantile paralysis of the encephalitic type, and some others which later proved to be of the spinal type, in which the spinal fluid was under increased pressure; these cases showed a fibrin clot and an increased number of cells per cubic millimeter and a large excess of mononuclear cells, usually lymphocytes. In other words, the characteristics of the fluid were exactly those of tuberculous meningitis except that the tubercle bacilli were not present. If the fluids were always examined as carefully as were those examined by Dr. Hemenway the absence of tubercle bacilli would rule out tuberculous meningitis. In routine hospital examinations, however, his experience was that tubercle bacilli were missed in about 90 per cent. of the cases of tuberculous meningitis, so that under these conditions the absence of tubercle bacilli was not of great importance in the differential diagnosis. A positive tuberculin test was obtained in a number of these same cases which later proved to be cases of infantile paralysis. The presence of a positive tuberculin test in this class of cases was still further misleading, and erroneous conclusions could only be avoided by a very careful examination of the fluid for tubercle bacilli.

Dr. Edwin E. Graham of Philadelphia said that the papers had covered the ground so thoroughly, especially in what was said regarding laboratory methods, that there was hardly anything left for discussion, and nothing to criticise. The standard set by Dr. Hemenway for tuberculous meningitis was a new one; the finding of tubercle bacilli in 135 of the 138 cases was remarkable. It meant that a new technique had been worked out which gave accurate and positive results. In the papers it was shown that the meningococcus was not always found at the first examination of the cerebrospinal fluid, especially if this examination was made early; it was a question as to just how early the tubercle bacillus was present in the spinal fluid in cases of tuberculous meningitis. It seemed to Dr. Graham, therefore, that any symptoms that were present early in cases of meningitis, and were not present when the central nervous system was not involved, should be of extreme value in assisting in an early diagnosis, and that it was possible in the enthusiasm displayed in examining cerebrospinal fluid to overlook clinical symptoms which might aid in making an early diagnosis. Brudzinski drew attention to two symptoms which he claimed to be present in meningitis and not present in other diseases: first, the passive flexion of the head forward caused flexion at the thighs, knees and ankles; second, there was a concomitant reflex of the leg on one side when passive flexion of the leg on the other side was made. During the last year and a half Dr. Graham said he had changed his opinion radically in regard to lumbar puncture. Formerly he had been willing to wait until the symptoms were fairly well pronounced. He could look back and remember cases in which he advised waiting twenty-four or forty-eight hours until the symptoms became pronounced. Now he thought this to be a mistake. Lumbar puncture should be done in every case where one had reason to suspect the presence of meningitis. In cerebrospinal fever this was absolutely necessary from the standpoint of treatment. In the early stages of a severe case of cerebrospinal fever, the rapid accumulation and consequent pressure of the cerebrospinal fluid itself had much to do with the presence of certain symptoms. Early and repeated puncture in these cases would at least ameliorate the symptoms. He had seen one case of cerebrospinal fever which later died of tuberculous meningitis. This patient, a girl, recovered from the cerebrospinal fever but was bed-ridden and finally died of tuberculous meningitis.

Dr. Samuel McC. Hamill of Philadelphia said it was curious how close one could live to facts without recognizing them. Until he had seen Dr. Holt's charts he had never been impressed by the fact that tuberculous meningitis showed such a seasonal tendency. In thinking over the dates of occurrence of fifteen cases which he had seen during the past year, he thought that all but two had been seen between February 1 and the end of May, corresponding, therefore, to the dates indicated by Dr. Holt's tables. Dr. Hamill said he was glad to hear what Dr. Holt had to say in regard to the von Pirquet reaction in cases of tuberculous meningitis. Like Dr. Holt he had gathered from the literature that cases of tuberculous meningitis failed to react; in every case he had seen during the last two years he had been able to demonstrate the reaction to his own satisfaction. He thought, however, that a great deal depended upon one's ability to interpret the reaction. In anemic and emaciated cases there might be practically no area of erythema, only the induration being present. In colored children the interpretation of the result was especially difficult because one must depend solely upon the circle of induration. He regretted his inability to discuss the last two papers, which were extremely interesting and highly valuable contributions.

Dr. J. D. Milton Miller of Atlantic City, N. J., thought that Dr. Griffith's figures were misleading in reference to the prevalence of tuberculous meningitis. He understood him to say that in the Children's Hospital of Philadelphia out of 239 cases of meningitis 121 were tuberculous. Dr. Miller's impression was, but without supporting figures, that about two-thirds of them were tuberculous. This was the impression he had when he looked back over the cases treated in his service. The figures Dr. Griffith gave might be explained by the fact that many of them ante dated the test of lumbar puncture; that many, therefore, were based upon insufficient evidence. In many cases the tubercle bacillus was not found and to the investigator this was sufficient to exclude tuberculosis. Anyone who had seen many cases of tuberculous meningitis must realize how variable were the symptoms and how much they differed from those described in the text-books, and, therefore, how impossible it was to make the diagnosis without resorting to lumbar puncture. It seemed to Dr. Miller that the papers read touched upon a moral issue, namely, that tuberculous meningitis was after all a common disease, a fact which was not recognized as it should be by the profession at large, or the public, to whom tuberculosis meant pulmonary consumption only. What had been brought out in the papers should prove a valuable weapon in the hands of those who were fighting tuberculosis. Physicians should impress upon parents how common tuberculosis was, how it affected little children, and how fatal it was; if the parents knew this he thought that they would be much more willing to give financial and moral support to the efforts now being made to stamp out tuberculosis than they now were.

Dr. John H. W. Rhein of Philadelphia said he was very much interested in the papers of the evening, and what remarks he had to make were rather a discussion of the subject than a discussion of the papers. He had recently made a study of nine cases of tuberculous meningitis in children in which a microscopical examination was made of the cortex of the brain taken from the region of the fissure of Sylvius, from the basilar surface

of the frontal lobe and from the paracentral region. A study of these cases showed that there was a cellular infiltration of the pia in all of these regions which seemed to be a process separate and distinct from the miliary tubercles present. These cases were readily divided into the exudative type, the proliferative type, and the mixed type. Sharp lines between these types could not be drawn. The cells in the exudative form consisted mainly of leucocytes, but there were also lymphocytes and plasma cells with a few connective tissue cells. In the proliferative cases the cells were chiefly of the connective tissue type, although some lymphocytes and plasma cells were found. In the mixed form the cellular infiltration was proliferative in type in one place and in another exudative in type. A careful study of the cortex in these places revealed the fact that in over one-half of these cases the cortex was implicated. Cellular infiltration, perivascular round cell infiltration, and microscopic hemorrhages were observed. These cases could be looked upon as instances of meningoencephalitis. Apropos of the contention of Hunguenin, Huttenbrenner, Cornil, and Hirschberg, and later by Hektoen and Diamond, that the origin of tuberculous meningitis was vascular and that the meningeal and other lesions were secondary, a study of the blood-vessels was made in his cases. Dr. Rhein found vascular lesions present to a greater or less degree in all. These consisted of a cellular proliferation of the intima of the small veins, one or two vessels being occluded. The vessel walls were occasionally found to be thickened. Perivascular round cell infiltration was observed quite frequently, and in one case the outer coat of a capillary had undergone hyaline degeneration. This change was rather insignificant on the whole and not comparable in any way with the blood-vessel change found in syphilis, for example. The character of the meningeal changes was such as to lead Dr. Rhein to the conclusion that the lesion was not a purely tuberculous one. He believed it was probably the result of a mixed infection and not one entirely due to the tubercle bacilli. The lesion of tuberculous meningitis in children differed from that found in the brains of adults dying from pulmonary tuberculosis with secondary involvement of the meninges of the brain cortex, which was often found accidentally at autopsy. If some form of antitoxin or vaccine could be discovered to favorably influence that part of the process which was caused by other microorganisms than the tubercle bacillus it might be possible to keep the patient alive a sufficient length of time to bring about a cure of the tuberculous process itself.

Dr. B. Franklin Royer of the Pennsylvania State Department of Health, Harrisburg, Pa., said that acute meningitis was not particularly difficult to diagnose. Out of 167 patients coming under his care in the Philadelphia Hospital for Contagious Diseases during an outbreak of epidemic meningitis, 147 had been properly diagnosed as of the epidemic type; five were tuberculous, the other the various acute types of meningitis, several of them following suppurative processes. The diagnosis in practically every instance had been made by the family doctor; in only a few instances had lumbar puncture or other scientific test been applied; in a few cases the Department of Health had rendered assistance; in a few resident physicians from the hospital had confirmed the diagnosis already suspected. Dr. Royer said he was very much interested in studying the chart presented by Dr. Holt, showing the frequency of tuberculous meningitis at the various age periods. In Dr. Holt's experience at the Babies' Hospital the tuberculous type prevailed in 70 per cent. of the cases having meningitis, while in Dr. Griffith's tabulation at the Children's Hospital in Philadelphia something more than 50 per cent. having meningitis were tuberculous. In the first instance Dr. Holt's tabulation was made in the Babies' Hospital, where children from three years and under were received for treatment. In the Children's Hospital in Philadelphia, where older children were treated, not so large a percentage of them were less than one year of age. Possibly had an analysis been made along exactly parallel lines, the difference would not have been great. In older children tuberculous meningitis was less common. A differential cell count was of value in studying the spinal fluid. With the majority of cells lymphocytes even without bacilli tuberculous meningitis might be diagnosed. Other important aids were valuable. Nothing had been said about an ordinary white blood cell count in the various types of meningitis. In the acute type of the disease, except where the organism was overwhelmed with toxines, and the patient was relaxed and flabby, the leucocyte count would run from 10,000 to 15,000 per millimeter up to 45,000 or even higher. In the tuberculous type, however, he had never seen such a rise in the leucocyte count. Dr. Royer said he did not mean to decry lumbar puncture, as he believed in a careful study of the spinal fluid in all cases; he regularly practiced it and he had followed through to autopsy practically every case dying under his care.

Dr. Herbert Fox of Philadelphia wished to report two rather interesting cases. The first was diagnosed as a case of gonococcus meningitis. This diagnosis had been questioned many times, but the determination in this case was made by a man of unquestioned ability and upon the facts that the organism could not be grown on the ordinary nutrient media, but required serum media, and that it produced conjunctivitis in the rabbit's eye. The differentiation between the meningococcus and the gonococcus should be made by serum tests and sugar fermentation. The second case was a man, nineteen years old, with septicemia. After about three or four weeks of his illness he had distinct symptoms of meningitis which disappeared within two weeks. Several days after the disappearance of this meningitis, a pseudodiphtheria organism was found in the blood. The patient died, but an autopsy was refused. This type of infection should be borne in mind in connection with middle ear disease in which the pseudodiphtheria organism was found. The question as to the increase of globulin was very interesting and important. One should not stop at a consideration of the globulin but should go further. There was a globulin formed in ordinary coagulation. Was it a globulin from nucleoalbumin or nucleoproteid, or were there any results of nucleoproteid cleavage? There was undoubtedly a spontaneous coagulation during the early stages of poliomyelitis. Wickman had lately changed his opinion as to the origin of poliomyelitis, formerly believing it to be hematogenous; he now considered it lymphadenous. In this connection one should not forget the above-named coagulation, indicating some alteration in the circulation early in the disease. More study along this line might give light as to the pathological physiology of many forms of meningitis.

Philadelphia Neurological Society.

At a stated meeting, held November 25, Dr. A. A. Eshner demonstrated "A Case of Tabes without Ataxia." The patient was a married man, thirty years old, who complained of pain and a sense of weakness in the lower extremities, with absence of knee-jerks, inequality of pupils reacting in accommodation but not on exposure to light, but with good gait and steady station and preserved coordination in the upper extremities. There were no gross sensory disturbances, no visceral phenomena, and no mental symptoms. The man admitted a history of gonorrhea, but denied syphilitic infection, although there was a scar on the penis, with glandular enlargement, and the Wassermann reaction was positive. The man had one healthy child four

years old, and his wife was in the fifth month of pregnancy. Drs. Charles K. Mills and W. J. McConnell demonstrated "A Case of Coarse Tremor of the Upper Extremity, with Atrophy and Fascicular Tremor of the Upper and Lower Extremities of the Opposite Sides." The patient was a man sixty-four years old, who presented a coarse rhythmic tremor of the left upper extremity of inconstant occurrence, resembling the tremor of paralysis agitans, but apparently increased by volitional movement. There was also some hypesthesia of the same member and doubtful wasting. The right lower extremity was slightly wasted and presented fascicular muscular contractions. The conditions were thought to be of hysterical origin. Drs. Mills and McConnell demonstrated also "A Case of Conal and Epiconal Lesion, with Perforating Ulcer of the Foot, and an Unusual Motor and Sensory Symptom-complex." The patient was a colored man, about twenty-five years old, with a history of syphilis. Drs. G. E. de Schweinitz and T. J. Fleming presented a communication entitled "Tumor of the Pituitary Body, with Complete Blindness Lasting Nineteen Days, Apparently Cured by the Administration of Large Doses of Thyroid Extract." The patient was a woman, thirty-nine years old, with a tuberculous family history, and in whom menstruation, previously regular, ceased at the age of twenty-one. She came under observation for progressive impairment of vision with narrowing of the visual fields and temporal hemianopsia greater on one side, and to which became added headache and nausea and paralysis of the third nerve on one side. A diagnosis of pituitary growth was made and mercurial inunctions instituted. Improvement, however, failed to take place until five grains of thyroid extract were administered thrice daily with intermissions over a period of several months. Vision was entirely lost in both eyes for a time, but it was subsequently regained. Under treatment the patient lost 18 pounds in weight, but this was subsequently restored. Dr. S. D. Risley reported "A Case of Bitemporal Hemianopsia with Akromegalic and Other Symptoms, Probably Due to a Pituitary Lesion." Dr. Risley demonstrated his method for detecting the Wernicke pupillary reaction, which consisted in the interposition close to the eye of a diaphragm preventing the entrance of a small beam of light into any other part of the eye than that half of the retina whose sensibility it was purposed testing. Drs. B. A. Thomas and Henry Beates, Jr., presented a communication entitled "The Successful Treatment of a Case of Tetanus." The patient was a young man employed about a stable and who was vaccinated upon the thigh. The wound became infected, with the development of symptoms of tetanus. The wound was sterilized as thoroughly as possible, and tetanus antitoxin was injected beneath the skin and into the spinal canal in amounts totaling more than 200,000 units, and from 2 to 5 c.c. of 25 per cent. solution of magnesium sulphate were injected repeatedly into the spinal arachnoid space. Under this treatment improvement set in after a time and progressed to eventual recovery.

The Miostagmin Reaction, Wassermann and Globulin Reactions in Internal Diseases of Syphilitic Origin.—G. Comessatti has examined nine cases of aortitis in persons of various ages, and obtained a positive Wassermann reaction in them all. In a case of aortic syphilis with insufficiency of the sigmoid and Argyll Robertson pupil, the reaction of Wassermann was positive with blood serum, and with the splenic transudate; negative with the cerebrospinal fluid, as was also the globulin reaction. In parasyphilitic affections of the nervous system the reactions should be made with the cerebrospinal fluid. In hemiplegia in young persons this reaction is of great assistance in determining whether the paralysis is of syphilitic origin. The same is true of early tabes. In luetic cases in which the Wassermann reaction was positive the globulin reaction was also present. In cases clinically negative the reaction of Wassermann was also negative.—*La Riforma Medica.*

Medicolegal Notes.

Medical Witness Cannot Be Cross-Examined As to Medical Authorities Except for Purposes of Contradiction.—In an accident case a physician testifying for the plaintiff testified that he found symptoms of spinal injury and as a foundation for his opinion that such an injury had been sustained said that he had found an anesthetic area about the lower portion of the spinal column, more pronounced on the right than on the left side. On cross-examination he expressly declared that he had never heard or read of a case where paralysis of spinal origin was on one side only. He was further asked if every authority did not state that paralysis of spinal origin must exist on both sides. Objection to this question was sustained. Examination of an expert medical witness as to the contents of medical works is permissible only when the witness has based his opinion wholly or partially upon his reading of such books; and then only when statements therein are not in harmony with the testimony of the witness. In this instance an affirmative answer would not have contradicted the testimony of the witness.—Griffith v. Los Angeles Pac. Co., California Court of Appeal, 111 Pac. 107.

Prescribing Cocaine to Habitual Users—Evidence of Similar Acts.—A practising physician was charged with having prescribed cocaine for an habitual user of the drug, not in good faith, and not as a substance deemed necessary for the proper treatment of the case, but in evasion of the Georgia act of August 22, 1907 (Laws Ga., 1907, p. 121). Under this act druggists cannot sell cocaine except upon specific prescriptions, conforming to a prescribed form, issued by lawfully authorized practitioners; and practitioners of medicine cannot prescribe the drug for an habitual user except in good faith for the necessary treatment of the patient. There was direct proof that the defendant had prescribed cocaine to an habitual user on several occasions. The only question was whether he did so in good faith, deeming the drug necessary for the treatment of the patient, or whether he was using his professional capacity and the issuance of the prescriptions as a device to evade the statute. The State showed that during the general period embracing the acts charged the defendant had issued a large number of prescriptions for cocaine and morphine. Witnesses testified that they would go to him and ask for a prescription, and that, without making any examination of them, he would write out a prescription for cocaine and charge them 25 cents for it. One of the witnesses who testified to receiving several such prescriptions from him was a woman; and the defendant, it appeared, had been acquitted on an indictment charging the illegal giving of prescriptions to her. It was held that it was competent for the prosecution to show such other offenses in order to prove the defendant's state of mind at the time of the particular transaction charged. This included the transaction for which the defendant had been indicted and found not guilty. The fact that the jury in that case decided that there was not enough proof to show beyond a reasonable doubt that the defendant acted criminally according to the manner and form in which he was indicted did not rob the facts attendant on the transaction of their inherent probative value.—Lee v. State, Georgia Court of Appeals, 69 S. E. 310.

Expert Opinion as to Testamentary Capacity.—In an action for the revocation of the probate of a will an objection was made to the admission as evidence of the opinion of the attending physician of the testatrix as to her mental capacity. The objection was made that his testimony was too uncertain and vague to support his statement that he did not think her capable during July and August of executing a valid deed or contract. He proved that he attended the testatrix once or twice a week for the last three or four years of her life. She suffered from Bright's disease, which was accompanied by heart trouble, severe attacks of asthma, and dropsy. Her condition, physically and mentally, was gradually failing. In the very early part of 1908 her mind was very feeble; she was forgetful; and on several occasions while she would be talking she would fall asleep. In June and July "it was very evident that she was failing physically and mentally right along." During that period she refused almost daily to take medicine. On cross-examination the witness said that she might have been more herself at times when he was not there, and that if she was in such condition she might have been capable. In answer to a question as to whether he could say positively that she was not able during June or July to

execute a valid deed or contract, he said that he had stated some time before that she was a woman of such peculiar temperament that anything she did not agree to would disturb her and make her incompetent to do anything of that sort, but he did not know whether anything of that description occurred in June or July. He adhered, however, to his statement that he did not think she could have made a valid deed or contract during the period in question. The court held that the probative force of the witness's testimony, while it may have been weakened, was not destroyed by the cross-examination, and that, considering the whole of his testimony, his opinion was not improperly admitted. It was held, moreover, that it was not essential that the statements which the witness made on cross-examination should have been included in a hypothetical question propounded to medical experts upon which they testified that in June and July the testatrix was afflicted with senile dementia and was therefore at that time incapable of executing a valid deed or contract.—Grill v. O'Dell, Maryland Court of Appeals, 77 Atl. 984.

Practising Without a License—"Suggestive Therapeutics."—A conviction for practising medicine without being registered, as prescribed by New York Laws 1907, c. 344, was affirmed by the Appellate Division, Fourth Department. It appeared from the evidence, without contradiction, that the defendant had an office, where he received patients and treated them for physical ailments and received compensation therefor; that he gave no medicine, and prescribed none; that he performed no surgical operations, and used no surgical instruments; that his entire treatment consisted of the laying on of hands and manipulation, breathing, and rubbing his hands together: and that his treatment was beneficial to his patients. The sign in front of his office indicated that his treatment was known and designated as "suggestive therapeutics." He had no license, and was not registered under the act. It was held that upon the evidence the defendant was practising medicine within the State as defined by the statute, and was guilty of a misdemeanor thereunder. His only contention was that the statute is a violation of the State and United States Constitutions, and in support of that contention it was said that he could do no harm, if he did no good. This contention was not sustained. The court said: "A patient may often suffer as well from a failure to prescribe proper remedies, or afford surgical relief promptly, as from making improper prescriptions or performing unskillful operations. A physician who holds himself out to treat patients for physical ills should know whether to do anything, and what to do, to relieve his patient; otherwise he should not be permitted to practise and impose upon the unfortunate sufferers who, like the poor, are always with us, and many of whom need the protection of the State against quacks in and out of the profession of medicine."—People v. Mulford, 125 N. Y. Sup., 680.

Privileged Communications Between Physician and Patient—Remoteness of Testimony as to Testamentary Capacity.—In a suit involving testamentary capacity to make a will dated in March, 1907, a physician who had attended the deceased occasionally during the four or five years immediately prior to January, 1907, was allowed to testify as to his physical and mental condition at the time of such visits. Objection was made to the competency of the witness under Iowa Code § 4608, providing that communications between physician and patient are privileged and may not be divulged. It was held that the physician was a competent witness, whether called by an executor of the will or by an heir who was contesting its validity. The same witness was also allowed to answer questions as to the mental condition of the testator, as to whether he was capable of forming a rational opinion as to the value of his business or property and as to his capacity to know and remember his obligation toward his children and grandchildren. The observations and conversations forming the basis of these opinions appeared to have occurred within a year or more before the will was made. It was held that the evidence was not too remote to be admissible. And, there being evidence tending to show senile dementia at the time of making the will and a gradual loss of mental capacity extending over several years, evidence that the testator was incapable of realizing the amount and value of certain property four or five years prior to the making of the will was held not to be too remote.—*In re* Walker's Will, Iowa Supreme Court, 128 N. W. 386.

PERSONAL EXPERIENCE WITH A VERY RESTRICTED DIET (RICE) IN ACUTE INFLAMMATORY DISEASE OF THE SKIN.

BY L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK.

PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, CONSULTING PHYSICIAN TO THE NEW YORK HOSPITAL, ETC.

FEW realize sufficiently the important connection of diet with disease; and in regard to diseases of the skin especially the subject has been greatly neglected. And yet a careful study of individual cases in private practice, with full notes, continually demonstrates the immense importance of diet in relation to certain dermatoses, and the great benefits often resulting from a proper control of this element of therapeutics.

Local causes, including parasites, undoubtedly play a very considerable causative part in many diseases of the skin, and even microorganisms within the system can induce cutaneous lesions. But from the almost omnipresence of large numbers and varieties of microorganisms, some of them distinctly pathogenetic, and the relatively few instances of infection occurring, thoughtful physicians are thinking and questioning why many individuals escape and others are affected, and also why a person is susceptible at one time, and most of the time escapes? There can be but one answer, namely, that the system or tissues are at one time in a condition to be susceptible, or furnish a proper soil for the development of such microorganisms, and at another are capable of resisting the attack; and proper liver action and active phagacytosis account for the difference. But the action of the liver and other organs and the condition of the blood are undoubtedly influenced greatly by the food and drink taken.

Again, advancing science shows more and more that many diseases, including certain of the skin, are dependent upon conditions of the vascular and nervous system, and these also are the result of deranged action of the chylopoietic organs, which are further greatly influenced by the character of the food and drink taken.

Thus it is that dietetics, in the broadest sense, which admittedly is at the bottom of all nutrition, is really of overwhelming influence in regard to the production of many chronic and some acute diseases, both of the skin and other organs, as close observation will continually show, and as could be abundantly illustrated; although it must be admitted that the subject has been as yet by no means accurately worked out.

The object of the present communication is to call particular attention to a special mode of diet which I have employed in certain acute inflammatory conditions of the skin with such inestimable advantage that I desire to commend it most strongly in suitable cases.

Fully five years ago, January 3, 1906, a gentleman aged 45 was referred to me with an exceedingly severe attack of bullous erythema multiforme, of which he had had two similar attacks within the previous three years. He had been eating heavily and drinking champagne, and the attack had begun at 4 o'clock on the previous afternoon, with a few small papules and much itching. Within the 24 hours it had developed violently, and both hands and wrists were the seat of intense inflammation, with great swelling, and covered with small and large bullæ, more or less hemorrhagic; the intensity of the process seemed to increase even while the case was being studied. He was in real agony from the burning and itching, and intense erythrism of the entire system; the pulse was 88, hard and throbbing, and the tongue coated. He was given a laxative and an alkaline diuretic, and was directed to confine his diet exclusively, for a few days, to boiled rice, bread, butter, and water. He was seen five days later and the change was remarkable; the eruption had cooled down at once, and the hands and wrists were then about normal, except for the exfoliation from the bullæ, and he had no discomfort. He remarked on the striking difference in the course of the eruption under this treatment from what he had experienced in the two former attacks.

Exactly this same form of dietary treatment has been given to a very considerable number of patients with acute inflammatory dermatoses, mainly in private practice, during these five years, with the most gratifying effect, so that I can now almost promise that in a very short time there shall be the greatest relief; and I am positive that the results I have secured in many of these cases far exceed anything I had previously obtained without it. In most cases there have, of course, been proper internal and external measures also employed, but in certain instances all other treatment has been avoided, and the results have been most gratifying from this dietary treatment alone, as in my own personal case, shortly to be mentioned.

In several cases of very acute general lichen planus and dermatitis herpetiformis the results have been very striking, also in acute urticaria, some cases of rapidly developing psoriasis with much congestion have been most favorably affected by this plan of diet.

Some of the most satisfactory experiences have been in patients with very acute generalized eczema, which is sometimes so exceedingly difficult to control. A case or two may be given in some detail.

A physician, aged 35, was first seen April 21, 1910. For ten years or more he had had eczema of the toes, with occasional eruption on the hands,

in the groin, about the navel, etc. Seven weeks before the visit to him in bed he had suffered from a burn of the left hand, which was followed very shortly by an eruption which spread quickly to the arms and body, so that when first seen the eruption was well-nigh universal. The hands and arms were swollen to double their size and covered with fine vesicles; the feet and limbs were also greatly affected, tense, and in some places exuding; so were also the body and face; the suffering from the burning and itching was intense, and for some weeks sleep was impossible, even with the strongest measures. He had always been a great meat eater, and had taken whiskey freely, and much beer in summer. He was placed on a diet of absolutely nothing but rice, bread, butter, and water, with some proper remedies. The next day the eruption had cooled down considerably, and five days from the first the change in his condition was remarkable; all tenseness had gone, and the hands and feet were about normal in size, and the skin peeling freely.

This same dietary treatment was given to an old gentleman aged 81, whom I had seen ten years previously with eczema, which had existed off and on for 21 years. When called in consultation, May 24, 1910, he had an acute exacerbation from which he was in great agony, and scratched excessively when he was stripped. He had been suffering for some time nervously, and had been given whiskey with eggs, etc., as he was thought to be very weak. Everything was stopped and he was placed on a diet solely of rice, bread, butter, and water, with some mild medical measures. In two days the relief was most marked, and by the end of four days he suffered very little from his eruption. He was then allowed a gradual change of diet, as will be mentioned later, and as I was going abroad I did not see him again. But I learned from his physician that the progress was steady, and in about a month he was almost free from his eruption.

Another striking recent case was in a lady aged 48, whose agony was excessive from acute eczema, which had been increasing for two months. In three days all had cooled down, and she was relatively comfortable, though, of course, it required some time to thoroughly overcome her trouble. The same remarkable result was seen recently in a woman, aged 40, in the New York Skin and Cancer Hospital. When presented at my lecture there was an intense raw, eczematous eruption on the left hand and arm, which were swollen to about double the size of the other, with also considerable eczema of the legs and elsewhere. One week later, when again shown at the clinic, the parts were practically normal. There was absolutely no internal medication, and only a little calamine and zinc lotion used later when most of the eruption had subsided under the rice and bread diet. Not long after I had presented this subject before the British Medical Association in London, in July, I had an opportunity of testing the diet in my own person, with results so striking that they are worthy of record.

On August 20 I began to suffer with itching and tension in the right hand with deep papulo-vesicles about the root of the little finger, necessitating the removal of my ring. This increased, day by day, affecting other fingers, also of the left hand. By the 24th I was exceedingly uncomfortable, and deep-seated vesicles had formed on the sides of the middle finger, third, and little finger of both hands, also small, deep-seated vesicles on the backs of some of the fingers and on the back of the right hand.

As I had had a similar trouble at about the same season of the year for a number of years past, I did not pay much attention to it, but used some simple remedies, including a calamine and zinc lotion, which had been of some service in former attacks.

When the eruption first occurred, some years ago, I attributed it to poison ivy, which was abundant around my country home, where I spent week-ends, but after a year or so this was excluded, as the eruption did not run the course of that trouble, and also I had sedulously avoided all contact with the vine. Nor has the disease seemed to be eczema, for the whole course of the eruption has always been different from that affection, and, even at its height or afterward, there has never been any tendency whatever to develop eczematous surfaces; when bullæ form they are tense and hard, with very thick coverings which are ruptured only with great difficulty, and often become somewhat hemorrhagic.

Nor did the eruption quite correspond to the course and appearance of dysidrosis or pompholyx, although, when at its height, on several occasions in past years I have repeatedly shown it to my dermatological confrères, and they could never make any other positive diagnosis than probably dysidrosis, a diagnosis which never satisfied me.

As it seemed, in other years, to come on late in the summer, when I had eaten very many peaches, I sometimes ascribed it possibly to that cause; but this year I had eaten hardly a single peach. I could attribute it only to some gouty and nervous condition, to which I am subject; curiously enough, it affected mainly the ulnar side of both hands, or at least its greatest intensity was there.

By August 25 I was at times in agony with the intensity of the erethitic condition of the hands, and spasms of itching and burning irritation would come on with the slightest touching; and if any attempt were made to rub or squeeze a part to relieve the terrible itching, there was then an uncontrolable desire to continue, and even to scratch until the condition was greatly aggravated; washing and wiping the hands brought on such a spasm, often many times daily. By this time there were quite large blebs, tense and not much elevated, on the sides of the fingers between the last two digital spaces of both hands, with much swelling of the fingers, so that they stood apart. These vesicular and bullous lesions were deep seated and multilocular, so that opening them in one place would not fully empty them. There were also many small, firm, deep-seated papulovesicles forming on the backs of most of the fingers, and more irritation on the ulnar side of the back of the right hand, near the wrist. In the later course of the eruption these tense vesicles would subside before much fluid was formed, and disappear without exfoliation. The larger, more bullous lesions were either punctured or accidentally ruptured, with some force; they would then dry down, the cover adhering to the tissue below, with absolutely no tendency to eczematous exudation. The course of the eruption on other occasions has always been to last several weeks, uninfluenced materially by treatment, internal or external.

On August 25, when the eruption was increasing pretty rapidly, and by no means at the height which it had attained during other attacks, I placed myself on a greatly restricted diet, such as I have already described. This consisted solely of rice

boiled in water, bread, butter, water, and absolutely nothing else. This diet I continued for five days, at each meal, three times daily. I used no other medical treatment, external or internal, except that I continued a mild mixture of acetate of potassium, nux vomica, and quassia, which I had been taking for some time as a tonic, and which had had no effect on the eruption.

The result of this sudden and radical change in the diet was remarkable; within 24 hours the tension, together with the burning and itching of the hands, was lessened, and there were no spasms of itching. In 48 hours there was further marked improvement, and I had very little discomfort, even on washing and wiping the hands. By the end of four days the blebs were flaccid and the swelling of the hands quite gone; there had been no new production of lesions after instituting the diet, and the disease seemed entirely checked. I continued the absolute diet, however, for one day more, in order to complete the five days which I had commonly found it best for patients to maintain strictly this plan of treatment. One week later most of the surfaces badly affected had exfoliated, leaving smooth, almost normal skin.

At the expiration of the five days I returned at once to ordinary mixed diet, with some coffee and tea, as I knew that I could again check the trouble should it recur. I also then began a mixture of strychnine, cinchona, and hypophosphites, with tablets of arsenate of soda, 1-30 grain, with each meal. After resuming ordinary diet I had at times very irritating pruritus on various parts of the body and extremities, occasionally causing considerable distress, but this ceased within ten days after discontinuing the rice diet and taking the remedies, and there was no tendency to the reproduction of the acute lesions described about the fingers, which became normal in every respect.

However, about a week still later the itching returned to the hands, and with it the development of the vesicles and blebs in the same localities, with some itchy papules on the backs of the fingers.

So I stopped all medication and resumed the rice, bread, butter, and water on September 15. The effect was the same as on the former occasion; the irritation ceased almost at once, and in three days the vesicles and bullæ had subsided and a rather more moderate mixed diet was returned to. A week later many of the affected places had desquamated, but the majority of the lesions disappeared without desquamation, and there has been no trouble on the hands since, now several months since the beginning of the trouble. There was, however, some general itching, in various parts of the body and extremities, for a week or two.

The *rationale* of the treatment described is very simple. For years my volumetric uranalysis have shown me that imperfect or deficient urinary secretion is connected with many diseases of the skin, and that faulty nitrogenous metabolism appears to be at the bottom of some of them; this is the more apparent in certain acute inflammatory affections. It occurred to me, therefore, some years ago, that by relieving the liver and kidneys as far as possible from the intake of exogenous proteids, by excluding nitrogenous elements of diet, the organs would be able better to remove the effete nitrogenous material from the system, and the diet was selected with that end in view. Hence rice, white bread, and butter were chosen as containing the smallest amount of nitrogen, while affording sufficient calories, and ordinary water, hot or cold, was freely supplied for the necessities of the system, as in all animal life. Milk was avoided on account of its large proteid element, and also coffee, tea, and chocolate, as having considerable xanthin products.

In giving this very restricted diet to a very considerable number of patients during the past five years with the results mentioned, in no instance have they seemed to suffer physically from the absence of the ordinary ingredients of mixed diet; indeed, I have been told time and again that they feel inexpressibly better, lighter, and freer, and more able to endure when under a vegetarian diet than before. In my own instance I noticed this. During three days of the first period I was at my country home and very actively engaged in pretty hard physical work, and felt a lightness and buoyancy unusual with me. I noticed that in stooping to weed and move stones I had not the dizziness which commonly hinders me from such work. My weight was 155¼ the day before commencing the diet the first time, 153 the morning after the expiration of the five days, and 155¼ two days later, on full diet, which is about my ordinary weight of late years, and at about which it has remained since.

An interesting point in connection with this almost perfectly non-nitrogenous diet relates to the urinary secretion. At the close of the fifth day of the rice diet my urine showed a specific gravity of 1.020, and an acidity of .315, a trifle above normal, and 1.9 per cent. of urea. That on the following morning gave a gravity of 1.025 and an acidity of .630, double the normal amount, with a slight excess of uric acid and 2.10 per cent. of urea; thus the average of urea for the day was 2 per cent., exactly normal. The next day, with a return to a full mixed diet, the night and morning urine stood at 1.022 and 1.024, and an acidity of .315 and .373 respectively, with 2 per cent. of urea in both, and still a little increase of uric acid in the morning specimen; while in the next 24 hours, under continued mixed diet, the urea and uric acid were a little below normal, which was also the case on the following day. Three days later the urine still showed the same characters, but with the urea below normal and the uric acid normal. (I have long suffered with more or less imperfect urinary excretion, with retention of nitrogen.)

We find, then, that immediately after the five days of non-nitrogenous diet there was actually an increase of the nitrogenous output, while on a return to a mixed diet, including meat at least twice a day, and coffee and tea, it was normal or even below normal. This can only be explained by the removal from the tissues of stored up and effete nitrogenous matter, the elimination of which gave relief to the cutaneous symptoms. There was a regular daily movement of the bowels during the five days of diet, but, as might be expected, the movements were rather small in quantity and of a very light color.

It is understood, of course, that this very light diet is not to be continued indefinitely, although I have had one patient who preferred to persist in it for about three weeks, because of the uninterrupted well being. My common direction is that this rice diet shall be continued for from three to five days, more commonly the latter. It is well then to return to a mixed diet rather gradually, and I direct that at first a moderate meal shall be taken at noon for a few days, with the rice morning and night. If all goes well a light breakfast is then given also, the rice

diet being continued for the evening meal for yet a while longer; in all this treatment caution is to be exercised against much indulgence in meat or any nitrogenous food. I find it well, in many of these cases, to keep the evening meal light for a considerable length of time, as the sleep is much better and less likely to be disturbed by itching.

When this treatment is first proposed or ordered there is always some remonstrance, and many questions asked as to other articles of food and drink; but experience has taught me that the best results are obtained by adhering strictly and absolutely to the articles mentioned, certainly for a few days, and invariably patients have expressed entire satisfaction with the plan and effects produced.

It is a little difficult to give any more specific indications in regard to particular cases in which this line of dietary treatment is applicable. As may be learned from what has preceded, it applies especially to acute inflammatory and congestive conditions of the skin, which may be especially associated with faulty nitrogenous metabolism. Many of the cases have been in high livers and those suffering from alcoholic poisoning, although in other cases there was no such condition, but only one of retained protein elements. It has been explained that the course of diet here indicated is employed only as a temporary measure, which is generally very effective in accomplishing a cooling down of an acute eruption, after which intelligent treatment is employed for the cure of the disease. There is no objection to repeating the very strict course of diet, should occasion arise, as in my own case, and not infrequently a prolonged vegetarian diet of varied character will be of the greatest service, as I have shown to be the case in regard to psoriasis.[1]

A word may be added in regard to the preparation of the rice, for this has much to do with the success of the treatment. It should be thoroughly cooked with water and not with milk, and generally it is better to have it dried out somewhat, so as to be flaky, by leaving it uncovered on the fire for a while. In my own case, however, I found that sometimes, when it was not so dried out, I relished it equally well and it agreed with me perfectly. The rice is freshly prepared with abundance of butter and salt, and eaten slowly with a fork, with perfect mastication; the bread and butter should also be well chewed, to secure the full action of the saliva. Water, hot or cold, but not iced, is to be taken freely, but not to wash down the food in the mouth.

During the active rice diet I avoid milk, as already mentioned, but later I find the greatest benefit in its use, when taken warm, pure, and alone, one hour before meals, as I have so long advocated.[2]

Diet is a matter which does not always receive the attention which it deserves from the medical profession; but with growing knowledge and experience its exceeding great importance in certain conditions of the system is coming to be more and more generally recognized. There are undoubtedly many difficulties connected with both the study and practice of dietetics, and it must be acknowledged that explicit data and directions are not commonly furnished by our text books or instructors in medicine; as indeed there is not a real unanimity of opinion in regard to many matters connected therewith.

[1]Bulkley: "The Value of an Absolutely Vegetarian Diet in Psoriasis," *Jour. Amer. Med. Assoc.*, Feb. 22, 1908.

[2]Bulkley: "On the Proper Employment of Milk, Especially in Certain Diseases of the Skin," *Dietetic and Hyg. Gaz.*, May, 1908.

The present communication is an attempt to contribute something definite in the line of the effect of dietary conditions in certain acute inflammatory diseases of the skin. For nearly five years I have employed the method here described in a very considerable number of cases of various inflammatory affections of the skin, and with unvarying good results, and in my own case, as narrated, the results were so absolutely conclusive that there can be no reasonable doubt as to the correctness of the position taken.

In conclusion I may say that in dermatology, as in surgery, attention to even minute details is of the utmost importance in order to achieve successful results; and if I have been tedious in presenting a relatively simple matter I can only hope that thereby I may lead some to give serious attention to a subject which, I am sure, may at some time prove of great value in practice.

531 Madison Avenue.

THE SURGICAL ASPECTS OF FILARIASIS.*

By CHARLES F. STOKES, M.D.,
SURGEON GENERAL, UNITED STATES NAVY.

When your president honored me with an invitation to present a paper he suggested that I select as a theme some feature of tropical service which might be of interest to you. Although until quite recently the manifestations of filariasis were little known beyond latitudes 35° N. and S., with a rapidly growing commercial and military association with our tropical possessions, these cases will sooner or later come before you.

When it is realized that 50 per cent. of the inhabitants of some of our island possessions are the carriers of these filarial worms the widespread extent of the affection will be appreciated. By no means all of those infected present clinical symptoms, or are even conscious of the existence of these parasites in their blood. It is only when their presence induces pathological changes that symptoms present themselves. It is not enough to demonstrate the presence of the *Filaria sanguinis hominis*, but its species must be identified in order that its clinical significance can be appreciated.

Three species of filaria will be briefly described, although but one of them, *Filaria sanguinis hominis Bancrofti*, so far as known at present, is identified in a causal way with the filarial diseases. By reason of the so-called "filarial periodicity" the embryos of these three worms are easily identified aside from their other characteristics. They are the *Nocturna* (*Bancrofti*), *Diurna* (*Loa*) and *Perstans*, respectively.

The embryos of the *Filaria loa*, or *diurna*, appear in the peripheral circulation at 8 o'clock in the morning, are most abundant at noon and disappear about 1. P. M. The embryos are very like the *nocturna* except the periodicity. The life history of this worm is not known. While it is not absolutely established, evidence shows that the *Filaria loa* is the adult form of the *diurna*. This organism is only found on the west coast of Africa. Clinically the adult forms are sometimes detected in the eyelids or conjunctiva, at other times in the subcutaneous tissues of the extremities, causing the so-called "Calabar" swellings, which are raised edematous patches, inducing itching and irritation, lasting several days and finally disappearing. The treatment is by excision, which the African natives accomplish with thorns. The

*Read at a meeting of the Society of the Alumni of Bellevue Hospital.

intermediate host is unknown. The mangrove fly and certain species of mosquitoes are, however, suspected. Practically 100 per cent. of the white population who remain two years in the upper Congo become infected.

The adult forms of *Filaria perstans* are found in groups in the connective tissues and fat of the mesentery and in the pericardial and retroperitoneal aortic fat. Its intermediate host is unknown. These worms are found in tropical Africa and Demerara. The embryos of the *perstans* differ from those of the *nocturna* and *diurna* in that they exist in the peripheral circulation at all times, and, too, they are not muzzled, so to speak, by an enclosing sheath and can penetrate the blood vessel walls with impunity.

In *Filaria nocturna Bancrofti*, we have the organism which has to do with filarial diseases and a somewhat detailed description of the adult and embryo forms of this blood worm will be of interest.

As already noted in the vast majority of cases, the presence of the *Filaria nocturna* gives rise to no symptoms whatever, but in some instances this harmony is somehow interrupted and then crippling, disabling and even grave disease may accrue. The red blood corpuscles are but little affected, while the leucocytes show a disproportionate increase in eosinophiles. In one case with a leucocyte count of 23,000 per c.mm. the percentage of eosinophiles rose to 22. The eosinophilia has a cyclical course following the presence of the embryos in the peripheral circulation. In one case the eosinophilia varied from 8 to 22 per cent, in another, with a leucocyte count of 10,000, the daily variation was from 3 to 15 per cent.

Even the lay visitor to the tropics is struck by the large number of crippled and disfigured individuals who are the victims of elephantiasis arabum, while those of us who have served in tropical hospitals are impressed with the great prevalence of other forms of filariasis, such as chyluria, varicose groin glands, lymphscrotum, chylocele, certain varieties of lymphorrhagia, orchitis, endemic lymphangitis and varieties of cellulitis, all depending on a varicose condition of the lymphatics attributable to the *Filaria nocturna*.

The adult, or parental, forms of filaria were first discovered by Bancroft of Brisbane, in 1876. They live in the lymphatics of the trunk and extremities, the sexes being found in association.

In our every-day laboratory studies of these cases we are prone to lose sight of the existence of these adult forms, for we seek out the embryos in the peripheral blood to confirm our clinical diagnoses. The presence of the adult forms in the lymphatic glands was very forcibly brought home to the writer while removing a tumor from the right groin of a Porto Rican who had been the subject of severe elephantoid febrile attacks. A mass the size of a small orange was dissected out and divided at the side of the operating table by an assistant, the cut surfaces presenting a grayish, mealy appearance. The specimen was set aside for future study. As the operation proceeded the anesthetist, a hospital corpsman, startled those present by calling out that the tumor was alive. Sure enough the cut surfaces seemed to be in motion, and here and there long, white, hairlike bodies were seen to protrude themselves and slowly coil up. The substance of the mass was largely made up of these adult worms. This experience appears to be quite unique and not duplicated in the literature.

These adult worms are from 2½ to 3½ inches in length and about the diameter of a horse hair; in fact, they closely resemble white horse hairs. Without going into a full description of these worms, it is of interest to know that the embryos in their development in the uterine cavity of the female so stretch and elongate the vitelline membrane that it becomes their characteristic enclosing sheath when they are finally extruded into the lymph stream. In this connection it is worthy of note that attacks of elephantoid fever and other complications are said to be due to the dislodgment by traumatism of ova not fully developed, which, by reason of their bulk, lodge in the lymphatic glands and there cause trouble. These febrile attacks clinically can be traced to traumatism in many cases.

The embryo forms, first discovered by Demarquay in 1863, which are found in the blood stream, are the diameter of a red cell and about 40 times as long; they are transparent and colorless, actively motile, possessing a thrashing movement, coiling and uncoiling with snakelike motions, causing great displacement of the red cells. The embryo has a sharp, tail-like extremity and a rounded head, with an ill-defined six-lipped armature best seen when the motility of the parasite has about ceased. The embryo worm is enclosed in a loose, transparent sheath somewhat longer than the worm, but generally conforming in shape to its body, which prevents the worm from penetrating the vessel walls.

If the peripheral blood of the human host be examined at the proper time, say at about midnight, from 300 to 400 of these embryos may be found in a single drop. We do not know why this periodic disappearance from the circulation takes place, but it has been found that the *Filaria nocturna* can be converted into a day parasite, in its peripheral appearance, by changing the sleeping habits of the host from night to day. In the case of the *filaria diurna* a change of sleeping habits has no effect on its peripheral presence.

Assuming that the parasites are evenly distributed throughout the blood, it is estimated that we may have as many as from 40 to 50 millions of these worms in an averaged sized man giving no more symptoms than the corpuscles themselves.

To follow the life history of the embryo filaria in detail in its intermediate host, the mosquito, would lead us too far from the subject; suffice it to say that every stage of this wonderful extra human existence of the parasite is perfectly demonstrable in the mosquito from the time of its abstraction from the human blood to its reintroduction to man at the instant of the insect's bite, when it finds its way again into the lymphatic trunks undergoing sexual mating and reproduction with the embryos passing into the blood stream while the parent filariæ, male and female, remain fixed in the lymphatic trunks. The particular variety of mosquito concerned in filarial distribution is *Culex fatigans*, an extremely common variety in most tropical countries.

The clinical manifestations of filariasis have been grouped by Manson under two heads—"elephantoid diseases" and "elephantiasis."

Chyluria, one of the so called elephantoid diseases, while at times extremely debilitating and disabling, is seldom fatal. Connected as it usually is with the presence of adult worms in the thoracic duct, it is liable at any time to be complicated by serious conditions arising out of the death of one or more of

these parasites, which may be followed by septic infection in a locality that can not be satisfactorily approached surgically.

Some years ago, while I was serving as surgeon of the battleship *Oregon*, in Japanese waters, a fireman who had been under treatment at our naval hospitals in the Philippines and in Japan for a supposed heart lesion was sent to us for service. After standing one four-hour watch, he reported that he was unfit for duty. A careful examination brought to light no abnormality of his organs; his temperature and pulse were normal, but his respirations were 55 per minute. He was fairly well nourished, thought somewhat anemic. In accordance with the writer's routine practice on board ship, a specimen of his urine was saved and found to be chylous with a tinge of blood. That night *Filaria nocturna* was demonstrated in his blood and later he was returned to the hospital with a diagnosis of filariasis. It is known that the filarial embryos accumulate in the blood vessels of the lungs and heart during the day and that the thoracic duct is often involved in these cases, still the writer was unable to account for this disabling rapidity of respiration, which persisted day and night while the case was under his observation.

Varicose inguinal glands are a very common result of the presence of the *Filaria nocturna* in the lymphatics. Both groins may be involved though one side is usually more pronouncedly affected than the other; it is rare for one side alone to be involved. These tumors, as a rule, appear between the ages of thirteen and twenty years and are apt to disappear between the ages of forty and fifty. From time to time they may be the seat of periadenitis and they then become painful, otherwise they cause little inconvenience. The axillary glands have been involved in rare instances.

Lymph-scrotum, like chyluria and varicose inguinal glands, is an indication of the presence of *Filaria nocturna* at one time or another. The scrotum may be moderately or extensively enlarged and be covered with herpetic-like vesicles and varicosities of variable sizes. There are inflammatory and febrile attacks occurring from time to time, attended with lymphorrhagia. It frequently coexists with varicose inguinal glands and chyluria. In a few instances the surgical removal of the scrotum has been followed by chyluria and occasionally by elephantiasis of the leg.

Chylocele. While serving in the tropics one is amazed at the number of scrotal lesions one is called upon to treat. Hydrocele is extremely and disproportionately common and is without doubt of filarial origin. In chylocele the tunica vaginalis is distended with a milky or reddish fluid similar to that found in the varicose inguinal glands and in lymph-scrotum. Filaria embryos are present and may also be detected in the blood. In Samoa the writer's experience has been that at the outset of elephantiasis of the scrotum an acute chylocele was the forerunner of the growth of the mass as shown by the crude efforts of the natives to relieve the condition. In every one of the many cases the writer has operated upon there were evidences of an attempt on the part of the natives to remedy the condition by an incision with glass, which had been followed by infection, involving and destroying the testicle on one side. The various chylous dropsies involving the peritoneum and pleura, the chylous diarrheas and various forms of cutaneous lymphorrhagia and circumscribed inflammation, or thickening of lymphatics, reported from time to time, were no doubt in many instances manifestations of filariasis.

Elephantiasis Arabum. This disabling and disfiguring filarial affection is extremely common in the tropics, especially so in our South Pacific islands, the Samoan group, where from twenty to thirty per cent. of the natives present evidences of the disease Davies in Samoa collected fifty-six slides from the night blood of fifty-six cases of elephantiasis and elephantoid diseases and found filaria in twenty-seven of his mounts. It is an interesting fact that the embryo worms can not be demonstrated in the peripheral circulation in the great majority of cases of elephantiasis Arabum. Manson's explanation is that the adult worms live in the lymphatic trunks of the extremities and that either they or their ova finally occlude the lymphatic glands and that the adult worms die after inaugurating a pathological condition which ultimately leads to the gross manifestations of elephantiasis, and in consequence naturally the embryos can not be found in the blood stream.

Elephantiasis begins with an attack of lymphangitis and an erysipelatous-like involvement of the skin, attended with severe constitutional symptoms. There is usually a sharp and prolonged chill, followed by high fever, terminating after a day or two in a sweat and often in a lymphous weeping of the involved skin. Some of the products of inflammation remain in the tissues and with febrile attacks recurring at intervals of weeks or months, the tissues, after a time, grow enormously and become permanently and densely hypertrophied. So dense does this tissue become that the writer has dulled a half dozen knives in the ablation of a moderate sized scrotum. The skin becomes rough and tuberose, warty or atrophied. When the leg is involved the process does not commonly extend above the knee. The lesion may end abruptly or fade off into normal tissue.

It is found on incising tissues affected with elephantiasis that the skin and the superficial layers of the subcutaneous areolar tissues are dense, white and enormously thickened even to the extent of from one to two inches in the scrotum. The deeper part of the superficial fascia is transformed into a yellowish blubbery-looking mass containing large veins and distended lymphatics from which on section gush blood, chylous fluid, or serum.

Elephantiasis affects various regions of the body the commonest sites being the legs or scrotum, or both; still the disease may involve the arms, breasts, female genitals, or scalp.

When the scrotum is involved the average weight of the tumor is from ten to thirty pounds; the writer has removed a mass weighing sixty pounds. It is not difficult to realize the disabling effects of these huge growths.

All of the filarial lesions are attended at one time or another by the so-called elephantoid fever. These febrile attacks are peculiar in that they are characterized by profound mental depression with suicidal tendencies in some cases. The subjects live in constant dread of the development of elephantiasis This was exemplified in the person of one of the leading financiers of one of our island possessions In this case the febrile attacks were in themselves severe and prostrating, and were usually attended with a lymphangitis and some swelling in the left groin, yet these conditions soon disappeared while a state of profound mental depression and apprehension persisted for a long time afterward. This pa-

tient has been under observation four years and is still free from elephantiasis.

A half-caste native came to the writer in his first febrile attack and presented for examination a hot, swollen, boggy forearm which later developed into a characteristic lesion of elephantiasis in spite of efforts to check the advance of the disease. Profound mental depression characterized this case as well. The diagnosis of these conditions is as a rule extremely simple.

In the treatment of filariasis prophylaxis holds the first place. There is no known means of killing the filarial worms when once they have gained a foothold. Every one in the tropics should sleep under mosquito netting, particularly those infected. Mosquitos should be destroyed as far as possible. The carriers of filarial worms should avoid all forms of traumatism, particularly those which might cause the parent filariæ to abort or which might cause rupture or set up lymphangitis in congested lymphatic areas.

Rossiter of the United States Navy, who has extensively employed tincture of chloride of iron in the treatment of elephantiasis, after the method of Du Broglio of the French Colonial Service, says: "I also consider it wholly within the range of probability that the widespread administration of this drug to the entire population in endemic areas might eventually eradicate the disease."

Chyluria is best treated on mechanical principles, aiming by rest in bed to reduce the pressure within the vessels of the renal or vesical lymphatic varix and, too, by a restriction of foods likely to increase chyle. After the subsidence of the chyluria a single tumblerful of milk will give ocular proof of the patency or closure of the varix.

Varicose inguinal glands should as a rule be let alone and the same may be said of lymph-scrotum, except when passing into pronounced elephantiasis, when it should be excised.

Chylocele should be treated precisely as we treat hydrocele.

Elephantiasis. The indications in elephantiasis of the scrotum are plain; the mass should be removed. The writer first dissected out both testes, and, as already noted, invariably found one destroyed, which he removed. The presence or absence of a complicating hernia was next determined, after which the mass was boldly ablated, safeguarding, of course, the penis and planning for its subsequent covering when necessary. The results were very satisfactory.

In dealing with elephantiasis of the extremities, many ingenious methods of treatment have been employed in the past without success. It is only quite recently that promise of success, even though partial, can be held out. Handley of the Middlesex Hospital buries silk threads in the tissues, aiming to establish new lymph channels and reports encouraging results; this method was employed by Draudt of Lexer's Clinic in a case of elephantiasis of the thigh and a decrease of twelve inches in circumference took place in eight days with a continued steady decrease at the last report ten weeks later.

Rossiter gives thirty drops of the tincture of the chloride of iron three times a day, and in the *Naval Medical Bulletin* reports on the results of treatment as follows: "I therefore conclude as a result of these experiments that tincture of the chloride of iron has a marked effect on the elephantoid process, decreasing the size of the affected parts and restoring function to an even greater degree. That its most marked effect, however, is on the attacks of elephantoid fever, these attacks being very markedly lessened in severity, the interval between attacks being very greatly lengthened, and in several of the cases cited the attacks have apparently ceased."

It is not at all unreasonable to believe that the distinguished Ehrlich, or some of his followers, will, in the near future, place in our hands a weapon as deadly to filariæ as the marvelous 606 appears to be to the vicious *Spirocheta pallida*.

CAMPHOR IN LARGE DOSES IN PNEUMONIA.

By LEONARD WEBER, M.D.,

NEW YORK.

On January 27 last I was requested by Dr. L. G. Weber to see with him a young married woman, who had always been well and strong, fond of outdoor life and had never been sick until she was taken with a chill during the night of January 25 about four hours after returning in a cab from the theater, the weather being cold. On January 26 at 10 A. M. her temperature was 103.5°; pulse, 92; respiration, 24. When we examined the patient on January 27 at noon the temperature was 104°; pulse, 108; respiration, 36. Signs of pneumonia in left upper lobe, some pain and signs of pleuritic effusion on right side. Heart showed normal dimensions; pulse soft and regular; second pulmonic accentuated; slight cough now and then, no sanguinolent sputum, considerable restlessness. Ordered infusion of digitalis 3ii every three hours, and an evening dose of pulvis Doveri, gr. v. On January 28 and 29 the temperature ranged between 102° F. and 104° F.; pulse, between 90 and 100; respiration, between 24 and 30; the patient, however, began to complain more of headache, had stitch in the right side, and a somewhat ominous angina-like pain in the cardiac region, with radiation into the left arm, though there were no signs of endocarditis. The left upper lobe became gradually consolidated.

January 30, at noon, she was somewhat cyanosed, markedly delirious; urine and stools were passed involuntarily. Temperature, pulse, and respiration advanced again. All objective and subjective signs constituted the symptom-complex of intense pneumococcic septicemia. There could be no doubt but that our patient would shortly die unless we could administer some pneumococcus serum, or vaccine, or chemical antitoxin which would help her to overcome an infection against which her constitution could not prevail. The serum, or vaccine, which had been used successfully in Boston at the Tufts Medical College and Hospital was not obtainable.

Henry A. Craig's paper on six cases of pneumonia in the aged treated with pneumococcus vaccine (Medical Record, Feb. 12, 1910) had not yet been published. However, I remembered Dr. A. Seibert's communication (*Münchener Medizinische Wochenschrift*, September 7, 1909) of favorable results obtained by him in treating twenty-one cases of pneumonia by hypodermic injection of camphor-oil. Of a freshly prepared solution, 20 per cent. camphor in oil of sweet almonds, we injected 2 hypodermic syringefuls into the outer circumference of the thighs every hour until 8 had been given each day, representing altogether about 30 grains of camphor on the 30th and 31st of January and February 1 and 2; altogether about 120 grains

of camphor in 4 days. January 31 the cyanosis had almost disappeared, pulse much stronger, though still 100, respiration 34, temperature 102° to 103°. February 1, fully conscious, bright color, good pulse, respiration and temperature the same, angina symptoms have disappeared, bowels and bladder under control again. February 2, pulse 90, temperature 99° to 100°, respiration 30, general condition good, consolidation of left upper lobe same. Soft râles began to be heard during the night of February 3-4. Resolution by lysis proceeded from February 4 to 9, and was complete on February 10. Temperature, pulse and respiration remained normal after that. On February 24 the patient was sitting up and sufficiently strong to permit us to aspirate the pleuritic exudate from the right side, ten ounces of reddish, turbid serum being removed. March 15 I had occasion to see and examine her, and found the local and general condition normal.

With the injections of camphorated oil, when aseptically done, the needle thrust well down into the cellular tissue, there will be no pain nor subsequent swelling; nor did we observe any irritation of bladder, kidneys, or stomach in the case, either at the time or subsequently.

132 West Seventy-third Street.

INFANT MORTALITY IN NEW YORK CITY.

By WILBUR C. PHILLIPS,

NEW YORK.

SECRETARY OF THE NEW YORK MILK COMMITTEE.

In the summer of 1910 infant mortality in the Borough of Manhattan, New York City, increased from 168 deaths per 1,000 births in 1909 to 178 deaths per 1,000 births. The causes for this increase were not apparent. A statement by the Bureau of Municipal Research charged the Health Department with responsibility through the carelessness and neglect of its nurses and physicians. Others blamed the excessive heat. Certain newspapers laid it all on the milk trust. In one section it was ascribed to the soil and to atmospheric conditions. The use of condensed milk was also brought forward. One writer even introduced a whiskey argument—but just what it was, no one in the general confusion of ideas seemed able to understand.

Meantime the babies died. Weekly reports, contrasting the death rate of 1910 with that of 1909, were published in the newspapers. The Commissioner of Health announced his intention to probe the subject through a Special Committee, and it was also stated that an exhaustive report on all matters relating to infant mortality in different boroughs of New York City was being prepared by the Health Department.

While all this was going on—while people were arguing about the various supposedly recondite causes of infant mortality—the absence of any need whatever, not only for an *increased* infant mortality rate, but for probably more than half of the present infant mortality, had been conclusively demonstrated.

In New York City as in Europe, it had been shown that infants need not die if pure milk can be distributed and if their mothers can be made to feed and care for them properly. The methods of this work had been established and even the cost of it had been determined. It is therefore interesting to know *what* were the results of the work at a time when all other methods appeared to fail and when public attention was centered on the frightful results of their failure.

In four infants' milk depots maintained in congested quarters by the New York Milk Committee, an average of 350 babies were cared for throughout the summer. Of these 350 babies only one died from diarrhea. The death was due to the obstinacy of a mother who, becoming impatient at the slow progress of her infant, left the station and weaned it on condensed milk. At a depot maintained by the Milk Committee in the Alfred Corning Clarke House at the corner of Rivington and Cannon Streets, 125 babies were cared for. Among these babies there were no deaths from diarrhea. One baby died of pneumonia, one of the whooping cough, and one as the result of the carelessness of its grandmother. In depots established by the Committee in Bloomingdale Guild, Henry Street and East 105th Street, and subsequently turned over to and maintained respectively by the New York Diet Kitchen Association, the Henry Street Settlement and Union Settlement, only five babies were lost from diarrhea during the summer.

These results obtained in districts where poverty was intense, where living conditions were intolerable, where congestion was rank, where great ignorance prevailed, and where the heat was probably as keenly felt as anywhere else in New York City, indicate that infant mortality is not due inherently to any of these causes. Soil and atmospheric conditions—even whiskey—exercised no baleful influence over these little ones. Their saving was not accomplished through the distribution of specially modified milk in individual feeding bottles because the Committee, in November, 1909, had discontinued the distribution of such a milk and the mothers in all the depots had prepared home modifications for their babies from whole milk throughout the entire summer. The purity of this milk undoubtedly was a great factor, especially as generous relief for the poor was provided by co-operating relief societies; but the main reason why these babies lived was the superior care and oversight which they received from the mothers themselves which came as the result of the sustained efforts of the doctors and nurses in the Committee's depots.

The part which mothers play in killing babies or keeping them alive has received too little consideration in discussions of infant mortality. Only recently have people begun to realize that the institutional care of babies is a failure; and that a shockingly large percentage of babies do not survive the ordeal of the gregarious organized existence of our hospitals, foundling asylums, etc. Outside of the small group of persons to whom this truth has come home with sledge-hammer force, motherhood has been cheapened and mothers spoiled by an excess of misdirected social, philanthropic and institutional assistance. Breast-feeding has been discouraged by the lavish distribution of commercially modified milk at low prices. Emphasis has been placed on percentage formulæ and pasteurization. We have discussed various mechanical, medicinal and organized methods of prevention as if they were so many pink pills to be fed alike to all pale babies; and in our hesitation as to whether philanthrophy or the State should administer these pills, have forgotten that the preparation of the food and the meeting of emergencies which are constantly arising can most sympathetically be taken care of by the mother herself.

That the mother is the natural guardian of her child; that even in the poorest, most squalid sections of the city she is abundantly able to care for her baby provided she can be given the necessary instruction (it seems ridiculous—the necessity of making this statement) has been conclusively demonstrated. Many of the mothers taught by the Milk Committee last summer and among whom the infant mortality was practically zero, could not speak English. Some of them could not read nor write their mother tongue. They were the kind of women over whom the average person is likely to hold up his hands and say "impossible." Yet we "put it up" to these mothers; we made them save their babies. It was not always easy. At times it required straight talking. Often it meant the assistance of friends and neighbors. But we, or rather they, did it—they made the best of existing conditions; and the results show how successful their efforts were.

The milk depot was an indispensable factor in this campaign. Here the nurse had her headquarters; here the mothers came to seek counsel and advice; once each week bringing their babies to be stripped, weighed, examined and prescribed for by the physician. Here daily the nurse kept in touch with each infant under her, thus directing her efforts where they were needed most, and here also, from time to time, were held those social gatherings at which the mothers received the stimulus of each others acquaintance and entered their babies in a friendly but life-saving competition of health.

The nurses employed by the Health Department, of whom 141 were detailed to special educational work from the department of school inspection, although they were faithful and conscientious workers, were greatly handicapped by having no centers provided them by the city from which to work. Their plan was to visit from house to house, calling especially upon mothers with new babies. This work, begun in 1908, was patterned after an experiment carried on in the 19th ward in the summer of 1907 by the New York Association for Improving the Condition of the Poor, which organized the New York Milk Committee. Since 1907, this educational work has been very extensively developed by the Milk Committee. The present plan of conducting such work from the milk depot centers, thus combining the home visitations with class work and central supervision, is by far the most effective scheme yet worked out. The Health Department realizes this and it is now making a determined effort to secure milk depots where its nurses can have their headquarters and from which they may carry on a more effective campaign to save the lives of babies.*

What results may be expected if this work is established?

Last summer the New York Milk Committee asked this question of a number of prominent physicians throughout the city. Their answers indicated that from 50 to 90 per cent. of all infants' deaths could be prevented by work carried on in infants' milk depots such as those above described. Only one answer fell below 50 per cent. and that was 40 per cent. The average reply was 60 per cent.

What is the cost of this work?

The cost of the educational features of this work varies in different places. If the work were properly organized, the cost per infant in New York City should not exceed $40 annually. The cost of relief should not exceed $10 per infant, making a total cost of $50 per year for each child.

Can the city afford this work?

The average cost of burying a baby in New York City, based on information given the New York Milk Committee by undertakers in all quarters of the city, is about $50. On the lower East Side many babies are buried at a cost not exceeding $20. In the Italian quarter where it appears less attention is given to a child's birth than to its funeral, the average cost is $50. Many babies receive more expensive funerals. The cost of these brings the average cost up to $50. At $50 per funeral the cost of burying the 8,000 babies who die needlessly each year in New York City is no greater than what it would cost to save these 8,000 babies.

How long, through misdirected expenditures, shall we continue to kill these babies?

105 East Twenty-second Street.

*In November, 1910, $40,000 was appropriated for fifteen milk depots to be run by the New York Health Department—five in Manhattan, eight in Brooklyn, one in Queens, and one in The Bronx. Home modification of infants' milk will be taught in these depots and methods of instructional work will be patterned after methods employed in the milk committee's stations.

CONCEALED CHANCRE OF THE MALE URETHRA, WITH A STUDY OF THIRTY-EIGHT CASES.

By CHARLES M. WHITNEY, M.D.

BOSTON, MASS.

PROFESSOR OF GENITOURINARY DISEASES, TUFTS COLLEGE MEDICAL SCHOOL; SURGEON TO THE GENITOURINARY DEPARTMENT, BOSTON DISPENSARY.

Every physician who has practised medicine for a number of years, especially in the larger cities, has occasionally met with cases of advanced and perhaps untreated syphilis, the origin of which was not easily explained. Eliminating at once from these cases those occurring in women (in which the initial lesion may be concealed owing to its situation in the vagina or on the cervix of the uterus), and considering only such cases as are found in the male, one is surprised to find the patients positively denying that there ever had been a chancre or indeed any ulcer upon the genitals. Careful questioning also fails to obtain a history of a lesion on the lips, on the tonsils, or on any other part of the body. Yet the syphilitic condition is there, and the question is, at what point did it enter the system in so insidious a manner as to escape observation?

As a part of the answer the writer has long been convinced that the primary lesion of syphilis exists in the urethra wholly concealed more frequently than is generally supposed, and the following cases are cited in support of this opinion. As a rule, the textbooks on the subject do not lay very much stress upon the condition, and the impression is left that there are usually marked subjective symptoms, such as dysuria or difficulty in urinating; or the objective one of discharge. One of the facts which this series of cases shows plainly is that a urethral chancre may be present almost wholly without symptoms of any kind when existing alone and uncomplicated by other venereal diseases. In this regard the writer was glad to find himself in accord with Col. Lamkin, who records in the "System of Syphilis" 481 cases of chancre, six of which were in the urethra. He further says that they are more frequent than is usually stated and that nine out of ten are taken for gonorrhea, which is probably due to the frequent complication with that disease.

Chancres in the male urethra are divided into two

classes: First, where this condition alone is present, and, second, where one has, as a complication, gonorrhea, or, as one of the cited cases shows, chancroid in addition. Considering those of the first class, we may safely say that there may be no symptom of any severity; usually there is a discharge of a thin mucous nature, which on microscopic examination shows a few leucocytes and epithelium. There is sometimes, but not commonly, a moderate purulent discharge. Dysuria is rare, there being usually only a little burning in urinating. The enlargement of the inguinal glands is not as marked as when the lesion exists upon the glans penis, due probably to the fewer lymphatic vessels. Urination is usually quite unobstructed. The first symptom which calls the patient's attention to the disease is the appearance of the secondary symptoms of syphilis, especially the roseola, the sore throat, and headaches. Should these unfortunately happen to be of the very mild type, they may be overlooked, and the patient is exposed to the horrors of untreated syphilis. If the patient has had a relapsing gonorrhea with gleety discharge he considers the new discharge, if slight, of the same nature and treats it by capsules or else disregards it. It is therefore perfectly possible that he may not consult a physician at all, a fact proven by several of my cases which were first seen when a roseola appeared.

In the second class of cases the patient usually applies early for the relief of his evident gonorrhea, and the physician, seeing a profuse, purulent discharge, perfectly typical of this disease, may or may not examine the secretion for organisms. Whether he does or not, he applies the appropriate remedies for the disease, which gradually yields, and before the time for any secondary symptoms of chancre to appear the discharge has ceased, and the patient considers himself well. If the eruption then appears he may disregard it or consider it due to the medicine, or again he may then consult another physician, who absolutely disbelieves his statement that he never had a chancre and places him under treatment. In this case both physicians are ignorant that they have been dealing with a concealed chancre. It is true that an eruption appearing during the treatment of gonorrhea may be due to the balsam of copaiba, and one of the most perplexing cases for diagnosis that the writer ever saw was one in which there was present at the same time a copaiba rash and the secondary roseola of syphilis, caused by a concealed chancre.

It can easily be seen that cases belonging to either one of these two classes may be overlooked by patient and physician in the majority of instances. It is of course perfectly absurd to expect the ordinary physician, and perhaps the specialist also, to palpate every case of gonorrhea to see if there is any induration present about the meatus or glands. Where he sees such a case, with pus pouring out from the meatus, for self-protection or for esthetic reasons he keeps as far from it as he can, and only palpates such cases when he uses early irrigations. For the purpose of finding out if there are any obvious objective symptoms which would lead one to suspect the existence of this condition, the writer has carefully studied this series of cases and has felt that there are three of them which are very frequently present, either separately or together, and which hitherto have not been described in medical literature, so far as he has noted. The first of these is a flattening of the end of the glans penis in the region of the meatus, sometimes being marked enough to resemble the cases of accidental removal of a portion of the glans in the ritual operation of circumcision among the Hebrews as seen in adult life. This condition is most marked where the induration involves the tissues of both lips of the meatus. With this we frequently see a swelling of slight degree of the meatal lips and an apparent constriction of its orifice. A condition closely resembling this is seen in double juxta-urethral abscess complicating gonorrhea, but this is much more tender and painful and usually ruptures spontaneously in forty-eight hours. Palpation shows a marked change in the tissues in cases of chancre, the induration being marked, while in the latter condition there is only a local tenderness limited closely to the lips of the meatus. The second symptom in frequency is a reddened zone on the mucous membrane of the glans penis extending back a quarter to a third of an inch. This has been most commonly noted in cases complicated by gonorrhea. The last of these objective characteristics of urethral chancre is a persistent edema of the prepuce, sometimes involving only a part of it, and is most suggestive where there is no obvious cause for it on the penis, or when gonorrhea is present as a causative factor it does not disappear as the condition improves.

The following cases show fairly well the ordinary history of this lesion as it has been seen in private and hospital practice:

Case I.—Urethral chancre with gonorrhea. A. B., 28 years of age, reported at the genitourinary clinic of the Boston Dispensary, in the service of Dr. A. L. Chute, on October 17, 1900, with the following history: First gonorrhea one year before, lasting a month. Present attack began seven weeks ago. No visible discharge, first urine clear with shreds, second clear; passes good stream. Urethra admits a No. 23 F. sound, but it causes much pain at the penoscrotal angle, where a stricture is present. October 24, 1900, slight discharge in the morning, first urine turbid with shreds, second turbid. Urethroscope shows reddened areas along anterior urethra, which are touched with silver nitrate. Complains of erythema, for which he is referred to the skin department. October 30, very slight discharge, first urine clear with shreds, second clear. Endoscopic treatment of reddened spots in anterior urethra. Urethra dilated to 25 F. November 16, slight discharge, first urine clear with comma-like shreds, second clear. Deep instillation, 5 per cent. silver; copaiba mixture. On May 11 he came again, this time in the service of the writer, and the above history, which is given because of its bearing upon this new complication, was referred to. He had called himself quite well except for a slight watery discharge, until the onset of the present attack, which began about a week before his visit, appearing four days after coitus. He now had a profuse, purulent discharge, containing many gonococci, both extra- and intracellular. He was placed under treatment, and the discharge diminished, but did not stop, and bearing in mind the history of stricture he was sent to the operating room for a urethral examination under appropriate precautions. The report showed a stricture just inside the meatus, admitting 18 *bougie-à-boule*, and 22 sound was passed into the anterior urethra. Posterior urethra not examined because of the presence of gonococci. This was on May 21. On May 24, 19 sound was passed with difficulty. On May 28, bougies 18, 19, and 20 were passed, as the steel instrument caused too much

pain. On the 31st, sounds 18, 19, and 20 were passed with much pain in spite of moderate cocainization, and some blood followed their use. On June 3, a 17 sound only could be passed and was followed by some blood and dysuria. In spite of careful dilatation, the stricture was steadily contracting, taking a smaller size on each sitting. On his next visit, June 7, I examined him and found the following condition: The lips of the meatus were somewhat swollen, and extending from them for about a quarter of an inch was a sharply defined reddened zone. In feeling the tissues beneath this a sense of resistance could be felt. There were small but hard and moveable glands in the left groin. There was a thin discharge, which showed on examination many leucocytes, bacilli, and extracellular diplococci, with epithelial cells. From these symptoms a diagnosis of concealed chancre of the urethra was made, which was confirmed in a week by the appearance of a roseola and of the secondary symptoms of syphilis. I have reported the case at length to show the absence of symptoms. Here was a case examined and treated by men who were treating many cases every day, who were thoroughly familiar with urethral examinations, but they failed to even suspect that anything more was present than an elastic and contracting stricture. The personal risk to a medical man who is treating such a case with ungloved hands is appalling.

Case II.—Urethral chancre with acute gonorrhea. E. F., 35 years old, consulted me on February 16, 1901. He had a history of several attacks of gonorrhea with various complications. No symptoms for two years previous to attack. For one month he had had a profuse, purulent discharge. On examination there was present a moderate purulent discharge, which contained intra- and extracellular organisms. On taking the smear it was noticed that the meatus looked flattened and that there was a reddened zone about it and that there was a moderate edema of the prepuce, more than would be expected from the subacute character of the inflammation. Digital examination of the lips of the meatus showed a hard mass on the left side extending toward the fossa navicularis. The glands in the left groin were enlarged and painless. A provisional diagnosis of urethral chancre complicating acute gonorrhea was made. During the next month the discharge almost disappeared, the glands slowly enlarged, and the edema of the prepuce continued. The indurated area about the meatus increased in size, but there was no difference in the freedom in urinating, nor was there any dysuria. On April 2, he began to have headaches and sore throat, and there was beginning general adenopathy. On April 14, a marked roseola appeared, thus confirming the diagnosis.

Case III.—Urethral chancre with chronic gonorrhea. C. D., 29 years of age, was seen in consultation with Dr. R. B. Rees, April, 1902. He had had several attacks of gonorrhea and had been treated for a chronic gonorrheal discharge. At the time of his visit to the doctor he had a mucopurulent discharge, containing leucocytes and extracellular organisms, presumably gonococci, although the gram strain was not used, as the case seemed perfectly typical of chronic urethritis. Examination with the *bougie-à-boule* showed a contracted meatus measuring only 12 F. There was no dysuria, but the stream was small. As a preliminary to proper examination and treatment meatotomy was done, and the hard, almost cartilaginous condition of the tissues was noticed. After the operation a series of strictures of small caliber were found in the anterior urethra. The cut surfaces of the meatus did not heal well, and the glands in the groin slowly enlarged on both sides, being movable and painless. Three weeks after the operation he was seen by the writer, and there was present a hard, firm mass at the fossa navicularis extending to the left lip of the meatus. On opening the lips of the meatus the mucous membrane had a grayish color; the inguinal glands were enlarged on both sides, hard, moveable and painless. A diagnosis of urethral chancre was made and confirmed in two weeks by the appearance of secondary symptoms of syphilis.

Case IV.—Urethral chancre with acute gonorrhea. T. C., 21 years of age, was treated at the clinic at the Boston Dispensary for an acute gonorrhea. There was no previous venereal history, and the duration was two weeks. A profuse, purulent discharge was present, so typical that no examination of it was made, and the early progress of the case presented nothing unusual. The discharge gradually lessened, and he did not complain of dysuria or difficulty in urinating. Six weeks after the first visit he called attention to a rash which was present upon his body which was a typical syphilitic roseola. More careful examination now showed nothing abnormal to inspection upon the penis; there were no ulcers, the glands on the groin were only slightly enlarged, but the end of the penis looked a little flattened. Digital examination showed a firm, hard mass involving both lips of the meatus and extending back to the fossa navicularis. Had it not been for the marked roseola the case would have been treated only as gonorrhea. If the eruption had been of a slight and quickly disappearing type which we occasionally see, the patient would have been exposed to the serious results of unrecognized and therefore untreated syphilis.

Case V.—Urethral chancre with acute gonorrhea. H. O., 23 years of age, second gonorrhea, two weeks' duration, treated at the clinic at the Boston Dispensary. There was a profuse, purulent discharge, of which no smear was taken. On his third visit, two weeks later, as he presented his genitals for inspection, a reddened zone was observed about the meatus, and a slight flattening of the end of the gland was present. Palpation showed a thickening of the left side of the meatus, not sufficiently indurated to be diagnostic, however. A personal diagnosis of urethral chancre was made, and during the next four weeks the symptoms gradually became more typical, and the diagnosis was confirmed by the appearance of the roseola on the forty-sixth day.

Case VI.—Urethral chancre with multiple chancroids and acute gonorrhea. X. Y., 26 years old, referred to me by Dr. W. A. Morrison. No previous venereal disease. Two weeks previous to the visit to me he had observed two small ulcers at the coronal sulcus, which appeared two days after coitus. Four days later a profuse, purulent urethral discharge began, and at the time of his visit was still present and showed both extra- and intracellular organisms. The two original ulcers had increased to six and were typical of chancroids, the edges irregular, the bases uneven, and the discharge from them profuse and irritating, causing a marked balanoposthitis with edema of the prepuce. The glands in the groin were very slightly enlarged and tender. Under proper treatment the discharge lessened. No new ulcers formed, and at the end of four weeks the old ones were nearly healed, and

there was no visible urethral discharge except a little in the meatus before urinating in the morning. The urine was clear and contained a moderate amount of light mucus. At this time on feeling for a possible induration at the base of the chancroid to avoid overlooking a mixed infection, an indurated mass was felt in the navicular fossa, well back from the meatus. The glands in the groin were somewhat enlarged, but not markedly so. At the end of six weeks the chancroid had healed without any induration, but the mass in the fossa had increased in size, and a roseola was present. The interesting feature of this case was the fact that the chancroidal ulcers did not become inoculated with syphilis, as we should expect had the initial lesion been acquired at the same coitus. On questioning him he admitted coitus with a different woman one week before the intercourse with the woman from whom the gonorrhea and chancroids probably had been received. It seems not unlikely that during this coitus he received his initial lesion, and the other infections were of later origin.

Case VII.—G. D. 16 years old, was referred to me by Dr. F. B. Percy, January 13, 1904. One week before he had noticed a little smarting during urination and the appearance of a slight watery discharge. No previous venereal disease. Last coitus one week before. The meatus was small, and on the left side of it was a firm mass extending backward toward the frenum. The prepuce was moderately edematous, which was rather striking in view of the absence of any visible local cause for it. The glands in the groin were not enlarged. During the next few weeks the glands of the groin slowly enlarged and the indurated mass increased in size, but there was no dysuria and only a little difficulty in urinating. Examination of the secretion showed a few leucocytes and epithelium, but no organisms. On March 17 a roseola and other secondary symptoms of syphilis appeared.

Case VIII.—J. M., 24 years of age, reported on May 23, 1905, with well-marked mucous patches on the mouth and with typical symptoms of secondary syphilis. His history was that six weeks before in Atlanta, Ga., he had discovered a rash upon his body, accompanied with sore throat and intense headache. There had been no sore on any part of the genitals, nor any urethral discharge. The glands in both groins were slightly enlarged. There was no evidence of a lesion elsewhere upon the body through which infection could have taken place. Mouth and tonsils showed no evidence of chancre, and there was no history of any. By careful palpation about the meatus a very doubtful thickening was made out. A small urethroscopic tube was inserted, and quite plainly to be seen upon the urethral floor at the fossa was a grayish healed ulceration. It was interesting to see the urethral walls fall so rigidly toward the central figure of the lumen of the tube, much like the induration of the prepuce.

Case IX.—X. Y., physician, 36 years of age, reported to me on January 3, 1909, with the history of no previous venereal disease. Three days before his visit he had noticed an eruption upon his body which he was at a loss to account for. The last coitus had been seven weeks previous to his visit, and there had been no local lesions anywhere upon his body. Mouth and lips perfectly normal. Upon examination, general adenophathy was present, and upon the body a faint but perfectly characteristic beginning roseola. To inspection the genitals presented nothing abnormal, although the right lip of the meatus may have been a little thicker than the opposite one. By palpation, however, a moderately firm mass could be felt about a half inch inside the meatus. Through a urethroscopic tube a healing ulcer with indurated walls was present, thus indicating the presence of a concealed urethral chancre. This case was the more interesting, as it occurred in a patient who was perfectly competent to notice any symptoms which would suggest a local lesion of this sort. There was not and had not been any urethral discharge, nor was urination painful or difficult at any time.

Case X.—H. H., 31 years old, colored. Previous history of two gonorrheas. Present attack four days' duration and began with a thin mucous discharge. Moderate dysuria. No examination was made of the discharge at the time, and he was placed upon the dispensary copaiba mixture. During the next week the discharge increased and the dysuria continued, and at the third visit the meatus was swollen and presented a rather flattened look, and the glands in the left groin were markedly swollen, but not tender. A distinct thickening and induration was present at the meatus. Examination of the discharge showed the absence of any gonorrheal organisms, as did several other examinations at later dates. As at this time, 1906, the discovery of the spirochetes by Schaudinn had been made and the statement was made that they were to be found best in the gland secretions, one of the largest glands was dissected out for diagnosis, and the presence of the spirochetes demonstrated. The appearance soon after of a roseola still further confirmed the diagnosis. In this case both the dysuria and the fairly abundant discharge were present, showing a marked contrast to most of the cases seen by the writer.

Besides these cases, the writer has seen twenty-eight others, making thirty-eight, in which the lesion has been recognized, but as the history of each is much the same, they will be referred to in a general way only. The size of the meatus seems to have nothing to do with the infection in such cases, the small or medium orifice predominating among those observed. Besides these cases many more have been seen in which the beginning of the chancre was out of sight, but in its progress involved the lips and then came into view, but they have not been included because they are *not* concealed.

Among the interesting cases was one occurring in dispensary practice, in which the chancre progressed slowly and unrecognized while the patient was having daily irrigation. This suggests the advisability of wearing rubber gloves in nearly all local treatment of these venereal cases, to avoid the great danger of syphilitic infection of the surgeon. Twenty-four of my cases have been complicated with other venereal diseases; fourteen have existed alone. When the patient is taking copaiba for gonorrhea and has a copaiba rash, considerable difficulty may be found in diagnosis if the roseola appear at the same time, as in one of the series already referred to, but discontinuance of the remedy and a diuretic will soon clear away the former, while the latter remains unchanged and progressive.

In six of these cases there was marked dysuria and in four of them there was some obstruction in urinating. From a study of this series of cases the writer desires in conclusion to state again the following facts, that concealed chancre in the male urethra is exceedingly difficult to diagnose and that

the classical symptoms of dysuria, marked urethral discharge, and obstructed urinary stream are not commonly found, but that in the majority of such cases one may have, separately or together, a slight mucous or watery discharge, a flattening of the lips of the urinary meatus, a reddened zone of mucous membrane in this region, edema of the prepuce without obvious cause, and, most important of all, the presence of an induration of the tissues beginning at one or both lips of the meatus and extending usually to the fossa navicularis, its most common situation.

TREATMENT OF PERITONITIS CONSECUTIVE TO APPENDICITIS.*

By J. J. BUCHANAN, M.D.,

PITTSBURG, PA.

PROFESSOR OF SURGERY AND CLINICAL SURGERY, UNIVERSITY OF PITTSBURG.

When a condition which requires surgical treatment is met by the recognized leaders of surgery with methods so divergent, so contradictory, as in the case of diffuse, free, or spreading peritonitis, resulting from appendicitis, no apology seems necessary for the recital of personal experience. A fairly thorough examination of the recent literature would lead to the belief that the great majority of surgeons have followed Dr. Murphy in his revival of Fowler's method with proctoclysis added.

Ochsner's Fabian policy, which has done so much to prove the power of nature to wall off an area of infection and absorb a widespread exudate, has helped greatly to reduce the mortality in these cases, and has a large following among surgeons. Joseph Price with his irrigation, eventration, massive gauze packing, and incomparable results, remains unique, no one outside his clinic seeming to succeed with his vigorous methods.

Another procedure is still to be reckoned with, namely, simple appendectomy, breaking up of adhesions, if any exist, to release pocketed pus and closure without drainage.

Reliance on the absorptive power of the peritoneum and closure of the sac without drainage in diffuse or general peritonitis originated with Robert T. Morris of New York in 1901. In his later practice he has ceased to close the peritoneum, but employs only a cigarette drain. In 1906 Franz Torek, also of New York, published† a series of eighteen consecutive cases of widespread, diffuse suppurative peritonitis, treated by appendectomy, elaborate washing with enormous quantities of water, and closure without drainage. Notwithstanding the favorable results of the closed method in the hands of Morris and Torek, this treatment appears to have had no very great following, and it is to call attention to its value that the present paper is written.

In the year 1907 the writer began to treat most of his cases of diffuse peritonitis, consecutive to appendicitis, by removal of the appendix, release of pocketed pus in advanced cases, dry mopping of the fluid within easy reach, and closure of the abdomen without drainage, sometimes using proctoclysis after operation, and allowing the patients to lie in the recumbent posture or turn on the side, as they might wish. Since that time he has operated on twenty-two patients by this method, all but two of whom have recovered.

*Read at meeting of the Medical Society of the State of Pennsylvania, at Pittsburg, October 5, 1910.

†Medical Record, 1906, Vol. LXX, 849.

The time limit assigned to papers to-day will not permit the recital of all these cases; but it seems essential to report some of them in order that the nature of the cases and the value and limitations of the treatment may be appreciated.

Mr. J. O. L. Sent by Dr. F. C. High of Wilkinsburg. Age, 33. Admitted to Columbia Hospital, September 16, 1910. Forty hours before admission patient had symptoms of perforative peritonitis with an indefinite history of similar symptoms for two or three days before.

Operation.—Incision through right semilunar line. Free pus widely diffused through the peritoneal cavity as high up as the liver, over toward the spleen, and in the true pelvis. Appendix very greatly thickened and enlarged, the size of the index finger, and adherent in the true pelvis. Part of the pus thick and yellow and other parts thin, like pea-soup. Adhesions of intestine, omentum, and appendix almost filled the true pelvis, extending over to the left side. Coils of intestine very much reddened and intestine thickened. Adhesions broken up as far as possible. Pus mopped out as much as was convenient. Appendix ligated at the base and removed. Abdominal wall closed without drainage. Patient is recovering and is almost ready to be dismissed from treatment.

Harry F., son of Dr. H. D. Fulton of Pittsburg, age 11. Admitted to Columbia Hospital February 12, 1909. Symptoms of acute appendicitis began twenty-seven hours before admission. Appendix gangrenous and perforated. Intestines much inflamed, and free pus, in large quantities, in the peritoneal cavity. At least a cupful evacuated of mixed varieties (some like pea soup, thick, and with curds).

Operation.—McBurney incision. No effort made to dry the cavity. Very little mopping. Abdomen closed without drainage. At the end of a week patient developed a temperature, and on the tenth day passed considerable pus by the bowel, although no localized sign of an abscess could be found on repeated examinations either through the abdominal wall through the rectum. Pus continued to pass by the rectum for four days. Patient recovered and was dismissed on the sixteenth day.

Charles M. Sent by Dr. Gabriel of Pittsburg. Age, 14. Entered Mercy Hospital April 25, 1909. Appendicitis began thirty-six hours before operation. Appendix gangrenous and buried deeply in adhesions to the outer side of and behind the cecum. Abdomen contained between a pint and a quart of fluid, partly thick and partly thin. Some coils of intestine covered with plastic lymph. Much fluid in the pelvis.

Operation.—Incision in right semilunar line. Appendix removed. Fluid mopped out with dry gauze. Large amount of fluid left behind. Abdomen closed without drainage. Patient recovered and was discharged on the twenty-sixth day.

William K. Sent by Dr. Aufhammer. Age, 26. Admitted to Columbia Hospital September 20, 1910. Symptoms of peritonitis began twenty hours before admission.

Operation.—Incision through right semilunar line low down. Appendix adherent deep in the true pelvis, perforated with a hole which would admit a large lead pencil. Peritoneum swimming with fluid, rather thicker than pea-soup. Proximal portion of the appendix bound to the bowel by adhesions. Distal perforated portion free. Appendix removed; pus partly removed in the neighborhood. No adhe-

sions except around the appendix. Pus seemed to come from all sides. Peritoneum closed without drainage. Abdominal wall closed with layer of sutures. Slender strands of iodoform gauze laid between the layers of the abdominal wall. Patient recovered and is ready for discharge.

The peritonitis in these twenty-two cases had been advancing from a few hours to seven days and it should be remarked that all the patients whose peritonitis was three days old or less recovered, and of the two who died the peritonitis had existed respectively six and seven days.

During the period covered by this series six advanced cases were operated on by other methods, the duration of whose peritonitis ranged from two and one-half days to three weeks. Of these cases three were treated by the Fowler-Murphy method and all died. Two were drained to the bottom of the pelvis and both recovered. One was moribund when placed on the table and died as soon as the tension was taken from the diaphragm by the outrush of gas, pus, and fecal matter with which the cavity was enormously distended.

In order to deal fairly with this subject and to arrive at conclusions which will stand the test of experience we must start, not with wide generalities, but with certain postulates with which all will agree.

1. Peritonitis is a condition which presents an infinite variety as to its extent, ranging from a slight area to a general involvement of the entire serous surface.

2. The tendency to spread and involve new surfaces depends on the size of the causative perforation, its location, the character of organisms, the resisting power of the protective body cells, and, above all other things, the treatment with regard to purgation.

3. There is a varying natural resistance to the process by the formation of protective and localizing adhesions and the absorption of exudates already formed.

4. Early formed protective adhesions are likely to wall off an area about the original infective focus with the formation of a single localized abscess with extremely favorable prognosis.

5. Late formed adhesions after widespread involvement are likely to result in multiple pus pockets scattered through the peritoneal cavity, attended with general septic infection and unfavorable prognosis.

6. The tendency toward favorable localization, general diffusion or widespread pocketing cannot be foretold in any considerable proportion of cases at an early period of the disease.

7. While the rate of advance varies in different cases the general rule is that the longer a progressive peritonitis has continued the more difficult is its management and the more unfavorable its prognosis.

Agreeing, then, with these postulates, it seems (1) that no single method of treatment could possibly be suitable to all cases, (2) that statistics of any method based on early cases are misleading, and (3) statistics based on the treatment of late cases must be unfair to any method.

The experience of the writer leads him to the following conclusions:

1. Cases in which the pus is generally diffused among the coils of the bowel, without any or with insignificant adhesions, peritonitis having existed for not longer than two days, are best treated by removal of the appendix, dry mopping of fluid within easy reach, and closure without peritoneal drainage. The mortality here is insignificant. So far no cases of this character have been lost in the writer's experience by the closed method.

2. Cases in which, in addition to general diffusion, there is pocketing of pus here and there through the peritoneal sac, will react differently according to the general condition present. It is essential that all enclosing adhesions be released and that the pocketed pus be taken care of by dry mopping or turned into the general cavity where it will be absorbed in favorable cases. In cases far gone with sepsis, on the other hand, this procedure is followed by a quickly fatal result.

3. Cases in which diffuse peritonitis still exists, but the physical signs point to an impending localization which will almost surely convert the case into one of localized abscess, may be left to the Ochsner treatment. These are the three and four day cases, and only the most careful discrimination will serve to distinguish them from the progressive ones with multiple foci. As experience with the closed method increases the Ochsner cases become rarer.

4. Cases apparently moribund, in which resistance has all but ceased, with blue, leaky skin, thready or absent pulse, subnormal temperature, and barrel-like abdomen, with loss of peristatsis, have nearly all died, whatever the treatment; the few exceptions being saved by a waiting policy with subsequent localization and drainage of abscesses.

The writer cannot close this paper without repeating the truism that the best treatment of an appendiceal perionitis is the preventive one—appendectomy on the first symptoms of an acute attack, and that purgation is the most deadly medication that can be employed in acute appendicitis or diffuse peritonitis.

INEBRIETY, ITS TREATMENT AND CURABILITY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

SUPERINTENDENT WALNUT LODGE HOSPITAL.

Inebriety is still considered a vague, doubtful disease in the early stages, more or less dependent on so-called moral causes, and never a distinct disease with marked physical characteristics, until the later chronic stages. A scientific study of individual cases brings out distinct evidence of a marked neurosis and disease at the beginning, and the subsequent development follows exact lines which may be predicted. The so-called moral causes disappear and have no place in the progress of the case. There are at the beginning some nerve defects, some toxine marked by depression, derangement of the functional and organic activities of the body also manifest in low vitality and exhaustion. These are pathological and psychological. The disease relates first to metabolism and maladjustment of the delicate functional activities of the body. It may come from defective growth, retarded development, inherited predispositions, poisons, and traumata which the conservative powers of nature cannot throw off.

Analysis of the Later Symptoms.—A symptom which appeals to all observers is that of intense spasmodic desire for alcohol, or a persistent demand for the effects of spirits. This symptom appears in many cases to be acquired or cultivated, that is,

growing from the first accidental use of spirits up to the present prominence.

This is called the preliminary period in which the use of spirits could not be traced to any particular desire. In another class of cases there is no preliminary period. The use of alcohol commenced abruptly, with or without any particular cause, but very soon the causes seemed to be a special thirst or demand for its effects, and this grew with its increasing use.

In the first class of cases a toleration was noticed, that is, the first effects of spirits did not appear to have any marked physiological action. Spirits were not attractive or repulsive. The increased heart's action seems to be quickly readjusted, and if large quantities of spirits are taken, or small quantities at frequent intervals, a distinct pathological condition follows. There are some abnormalties back of this use that may develop into distinct depression and conditions that will call for spirits again. To many persons the first effects of spirits are of comfort and relief. A species of fascination follows, different from that of any other drug. The sense of good feeling, exhilaration and strength seems ideal, and the desire to repeat it is beyond the power of resistance. This peculiar condition is pathological and points to a distinct defect of metabolism and nerve function, or in other words, a pronounced neurosis marked by depression and derangement. There is a third class of persons in which alcohol and its effects are repellent. Both the taste and effects produce antagonism, headache, depression, and an uncomfortable feeling. They are distinctly poisonous.

This is probably a normal condition. Any drug that raises the heart's action, increasing the flow of blood and diminishing the vasomotor control, would naturally be repellent. Experience shows that many persons in whom the poisonous effects of alcohol are pronounced at first very soon acquire a toleration and fascination and become inebriates. A large percentage of cases manifest at first physiological fascination, or rather a degree of comfort and relief from its use. Unlike any other drug, its use creates a demand for it which increases to a craze and obsession.

There is some neurotic defect which this drug not only covers up, but increases. This defect is both functional and organic; organic, from inheritance from local conditions of irritation, from traumatism, toxemia, defective cell growth, and so on, through a long list of causes. A great variety of causes incident to life of the present day seem to prepare a field for growth of the toxins of alcohol, and the narcotic effects which check sensation and give delusive symptoms. The disease is a distinct neurosis, both organic and psychic, and the use of alcohol is a symptom of this condition as well as an active cause in producing distinct degenerations both local and general that are due in part to alcohol and to the conditions which precede it. It will be evident from this point of view that a greater variety of causes including traumata, toxins, defects of cell and tissue, psychical failures, and organic derangements, all contribute and develop into the desire for spirits to cover up and conceal the conditions present.

Treatment of Symptoms.—In the opinion of many persons the disappearance of the desire for alcohol is the cure. Hence this particular symptom and its control and subsidence is the central object of all treatment. An immense literature founded on this theory is going out to the public, the central object of which is that alcohol is the central cause of all inebriety. Remove this and the inebriety disappears.

The tremendous efforts to suppress the saloon are based on this theory. Many volumes describe the moral causes of inebriety; discuss weak will-power and its treatmtent, and give great prominence to so-called moral training. This is not supported by any scientific study. Those who are studying some particular combination of remedies that will destroy the appetite for spirits are equally belated in exact knowledge of the conditions calling for help. The removal of alcohol is only taking away some of the causes which may be insignificant compared with the real conditions. Producing disgust for spirits in the mind of the patient does not develop strength, and cannot be called a cure.

Giving narcotics for pains, regardless of the causes, is neither rational nor scientific. Treating the desire for alcohol as the disease is equally irrational. The drink symptom dies out in the periodic cases, then breaks out again. Innumerable drugs can be given which will break up the desire for drink, produce psychic disgust and repulsion, but unless the other causes are reached this is only transient.

Scientific Treatment. In all cases of inebriety there are two acute conditions to be recognized in the treatment. One is congestion with a tendency to hemorrhage. The other is paresis and narcosis. In the former there is diminished circulation of the blood, constant dehydrating and protoplasmic action of alcohol on the cell and tissue.

With this there is irritation from the accumulation of toxins and waste products. As a result local inflammations, such as gastritis, nephritis, cirrhosis, and many other direct and indirect irritations and inflammation. In the second, the paretic condition, there are marked depression and derangement of the sensory activities, with a diminution of nerve force, particularly of the branches of the pneumogastric nerves. This is noted in pnuemonia, derangement of the surface circulation, and sudden variation in the functional and organic activities of both body and brain. Drugs that complicate these conditions are to be avoided. Drugs that seem to act as substitutes for alcohol are pure fictions.

The theory that spirits have braced up and increased the activity of the body, and that their removal will be followed by depression is delusional. In reality, just the opposite exists. Spirits have acted as a narcotic and depressant, and their removal is a necessity, a relief, and withdrawal of active causes in their restoration. Remedies given to produce revulsion to the taste and craving for spirits are numerous, but many of them are more dangerous to the organism than spirits. Thus combinations of strychnine and atropine used indiscriminately in every instance are almost certain to produce ill effects in many cases. This is confirmed in the examination of the patients who were treated by specifics, who exhibit motor palsies, defective vision, and a variety of symptoms that can have no other origin except that of the poisonous action of the drug. Many of the bitter tonics, particularly infusions of quassia, cinchona and gentian, will very quickly produce a distaste for spirits and allay the craze or desire for the effects of alcohol. These drugs are harmless and are very practical in many ways, but the results are only temporary. One can go down to the lowest stages of chronic inebriety and with bitter tonics and salines destroy the taste

and appetite for drink in every instance, but this would return after a time. Some of the quack schemes are based on these facts.

Scientific treatment must begin and be based on a study of the conditions which have preceded and provoked the use of alcohol as well as the injury and conditions which have followed. From this point of view the means and methods to remove the early causes and break up the present conditions and direct them towards recovery should be a matter of much certainty. A number of very remarkable instances where trauma produced a distinct defect which was manifest in an intense desire for spirits have been reported. Thus the removal of necrosed bone, trephining the skull, in case of an old fracture, to relieve pressure on a nerve, or irritation from some mechanical cause, have been followed by a complete cessation of all desire for spirits. A chaplain in the army who was wounded in the Spanish War, developed inebriety with criminal instincts, and for many years his life was a continuous excess of alcohol and crime. He died in prison, and the post-mortem showed the fragment of a ball pressing on the nerve centers.

A change in diet and sleeping rooms has been followed by a complete recovery, not only of the drink impulse, but the previous ill health of the person. Change of occupation is another factor most essential in many cases. The removal of the early depressing causes, or factors which have lowered vitality and diminished the power to endure suffering and pain is often followed by absolute cure.

Combinations of drugs given with an indefinite object and but little knowledge of the exciting causes have a shotgun inaccuracy that is very likely to produce far more injury than good. Probably diet and psychical surroundings are very active causes in perpetuating and developing the neurosis. This is evident from the result of change of surroundings and giving up meats and other proteid foods. Elimination is the first practical object in the treatment. The reason for this is that all inebriates are more or less toxemic, and suffer from derangements of circulation, particularly on the surface of the body.

The natural eliminative measures are greatly deranged. Baths of various kinds, the most effective of which are the electric and hot air baths, are the most useful and practical measures. The purpose is to get relaxation of the skin, increased activity of the emunctories and surface circulation. In many instances this is sufficient to break up all desire for spirits for a long time.

Electricity in the form of the static breeze and the concentrated light is a remedy of great value with startling possibilities for the future. It increases oxidization, diminishes the toxemias, as well as the congestive areas, and assists in the restoration of the cutaneous circulation.

Besides the bitter tonics in the form of infusions which are particularly valuable at the beginning, the phosphates and various other mineral drugs are remedies of the greatest practical value. Where a specific history is present, the iodides can be used in large doses with mercury.

The great object is for remedies to break up the present condition and change the original condition for the relief of which spirits were used. In baths and electricity there are certain modalities which can be used to overcome conditions of exhaustion, nerve poisoning and starvation, particularly if this is associated with rest, diet and change. The old term "constitutional remedies," including everything that will favor the restoration of the lost energies, and assist in the return of the activities to a normal condition, describes in general the course to be pursued. Narcotics and anesthetics addressed to the drink obsession in most instances increase the narcotism and derangement, and diminishes the restorative powers of nature.

Alcohol used as a narcotic and anesthetic is followed by distinct degenerations of which senility, cirrhosis, and various forms of paralysis with nerve exhaustion are the direct results. Giving similar remedies only increases the condition and conceals the actual breaking down process. It is very evident that no particular drug can be used as a specific, and its only value is when directed wisely in particular cases to accomplish special results.

In a certain number of cases special drug treatment has been literally destructive in that it excited other conditions and provoked degenerations that did not exist before. In all instances drugs have a limited value and this may be increased when associated with a variety of means and measures.

The drug treatment has a very important place, particularly at the beginning of the case, but must be used with distinct reference to the early and original causes which have formed the neurosis of inebriety. Hydropathic and electrical treatment and also psychic treatment are capable of very much larger application and more practical results. Beyond this there is a vast range of causes, the removal of which constitutes the highest kind of therapeutic science and judgment. Thus, change of occupation, change of climate, change of diet and change of thought, purpose, and ambition have been followed by complete recovery, and lives of great usefulness. The very evident conclusion which a careful study of these cases indicates is that there are no specific drugs or no specific modalities of any kind that have a universal application, but that this neurosis and disease must be treated by a great variety of means and measures. These may be included under the terms of home and sanatorium surroundings with hydropathic, electropathic, photopathic, hygienic, dietary means and measures applied with reference to both the physical and psychical conditions present.

Curability.—Notwithstanding the present confused state of means, measures and drugs used, the curability of inebriety is becoming more and more pronounced. The experience of reputable authorities with large practical experience shows that from 20 to 35 per cent. of all persons treated along rational, scientific lines recover. This in itself is evidence of greater possibilities from a farther and more exact study.

The delusive theory that has been the basis of most of the cures that aversion to spirits and total abstinence are all that are needed is supported by many cases. The empiric with his mysterious specific drugs appeals dogmatically to many cases cured. The pledge and prayer cure refer to many cases that are apparently cured. Moral and educational training and all sorts of means and measures have been followed by total abstinence. The literature of the results of these measures is exceedingly voluminous and of intense interest. Thus the Washingtonian Movement of 1845 pledged three million persons who remained abstinent afterward for periods of one week to a lifetime. Great temperance crusades have had about the same results. The empiric cures claiming 98 per cent.

restorations, and all the various means and measures by drugs and by psychical means all point exultingly to the number of persons cured. Years afterward the vast majority of these persons relapsed and disappeared. Each new measure or remedy fails in the last analysis, although many persons are practically cured. The great underlying fact in explanation has been overlooked. It is this, that the drink craze is a self-limited symptom and dies out in a large number of cases, with or without any particular exciting cause.

Innumerable instances are recorded where persons supposed to be in a chronic condition suddenly stop all use of spirits and remain temperate for the rest of life. In reality some psychological and physiological change has taken place in the nerve centers, and while the original exhaustion and fatigue remains, the desire for relief by the use of alcohol passes away. In explanation of this sudden disappearance of the drink craze, they ascribe as the cause the last thing used, no matter how frequently the same measure has been applied before. Thus the faith cure, the prayer cure, the pledge cure, the gold cure, and every other form of means and measures are credited with final curative powers. A certain number of persons continue free from the use of alcohol. Others may relapse, but the original drink craze disappears. The relapses may be not a return to the drug taken before, but the development of other obsessions and conditions of disease. In all this there is the strongest evidence of the curability of this neurosis. The question is often asked, what is the future history of persons on the subsidence of the drink craze? Is cure and recovery a permanent condition in which their former health and vigor is restored? The general answers to these questions come from a careful study of several different classes, particularly the history of the early conditions. First there are the neurotics with defective heredity and a distinct neurotic and psychoasthenic condition. The disappearance of the drink obession is followed by relief of the toxic conditions, but other neuroses and states of degeneration, particularly paranoia, hysteria, mental instability, states of dementia and other mental troubles with invalidism and local impairments follow during the rest of life.

A second class is one in which the drink craze is preceded by some profound derangement of the brain and body from trauma or disease. Here the subsidence of the drink symptom and the removal of the active exciting causes are followed by a great improvement and pronounced restoration. Often such persons occupy prominent positions and do much work, but they all suffer from general impairment and diminished vital resources.

A third class of persons in whom the drink craze follows metabolic changes and derangements improve immensely when this dies out, but diseases of the lungs and other organs are very apt to follow from the slightest exciting causes. Derangement of nutrition always predisposes to hemorrhage and deranged circulation is followed by vasomotor paralysis. The heart and arteries are enfeebled. There are low vitality and sensory defects and with them a degree of toxicity and starvation that may break out at any time. The curability of such persons depends on the recognition of the original condition and the exciting causes and their removal and means and measures that will assist in restoring the body to its normal conditions.

The fact that alcoholic symptom will die out itself from causes unknown should be considered in any measure of treatment, and the still greater fact that the neurotic defect and psychical impairment of the individual can be overcome, diminished and so far broken up as to enable the person to do good work, and take place among the active workers of the world, is one of the greatest incentives for renewed and exact therapeutic means and measures.

The best statistics of to-day indicate that over a million persons are suffering from drink and drug neuroses diseases that are practically curable, as consumption, typhoid fever and other diseases. The assertion is made with great confidence that inebriety is preventable and will be stamped out in the future as positively as fevers and epidemic diseases. These are not theories, but are based on a very large number of facts which have no other meaning. In view of this, is it not astonishing that so little is done that can be called scientific and rational? Our duty is clear not to find drugs or combinations of drugs to produce startling, unknown effects, and to study their application, but to find the causes, acute, chronic and predisposing, which have made it possible to use spirits with pleasure and to produce a certain fascination for their effects. It is from a study of these that we shall determine the best means and measures for the cure of this vast army of unknown diseased neurotics.

Oxaluria and Diabetes.—R. Roubitschek found that of eighty diabetics one-third showed an increased excretion of oxalic acid. An abundant meat diet increased this excretion, while a carbohydrate diet had no effect on it. —*Prager medizinische Wochenschrift.*

Radiotherapeutics of Fibroma Uteri.—In many respects the high hopes that were raised in the beginning of the use of the *x*-rays, as to the cure of malignant and non-malignant tumors, have not been realized. It is interesting to find an author who claims that a definite cure of uterine fibroids can be obtained by the use of the *x*-rays provided the applications are begun before the seventh year of the growth. H. Bordier states as a result of his experience in the treatment of uterine fibroids that this is the case. The treatment may be applied in such a way as to give no results, while if the technique described by the author is carefully followed the complete cure may be obtained. Bardachzi obtained a decrease in size, an arrest of hemorrhage, and a rapid improvement of the general condition. The rays cause the cells of the fibroma to atrophy, and the diminution in volume appears even when menstruation is still continued. In some cases the fibroma entirely disappears and the menses continue; this occurs in young women especially, where it is not desirable to castrate or remove the uterus, and where the tumor is small in size. The best effects of the rays are obtained in small fibroids of recent growth. Good results are also to be expected in fibroids reaching to the umbilicus, provided they have been present less than seven years. Small fibroids of any age that are accompanied by much hemorrhage are well affected by the rays. In recent fibroids the regression occurs in four or five months, and the menses grow less and finally disappear. In hemorrhagic fibroids the result is even quicker, atrophy occurring as soon as the Graafian follicles have been affected. In fibromata older than seven years operation is to be preferred to treatment by *x*-rays. The less potent rays are filtered out and the treatment is given first over the two ovarian regions, and then over the middle line of the abdomen at a point between the pubis and the umbilicus. Every other day the applications are made to the different regions.—*La Presse Medicale.*

THE OXYPATHIC DIATHESIS.

THERE is a growing tendency, noticeable, particularly in French and German medical literature, to attribute to inherited constitutional factors an important rôle in the production of disease. The diatheses of the older writers are again coming into vogue, partly under new names, and coordinated or harmonized with the results of modern experimental investigation. French clinicians have placed considerable stress upon the socalled arthritism. In early infancy this is regarded as responsible for many cases of poor development, associated with eczema and catarrhal conditions of the upper and lower respiratory tract. In childhood the manifestations of the arthritic diathesis are still more varied, including enlargement of the tonsils and adenoid growths, obstinate attacks of bronchitis associated with asthma, eczema, and periodic vomiting. With the approach of adult life there are added acne and psoriasis, pseudomembranous enteritis, migraine, neurasthenia, diabetes, gout, nephrolithiasis, cholelithiasis, neuralgias, myalgias, nephritis, and various forms of dyspepsia. The arthritic individual is predisposed to rheumatism and obesity. The genesis of arthritism is regarded by the French as partly the result of heredity and partly the result of an excessive diet of meat, fat, and bread, with a scarcity of fruit and vegetables. Overindulgence in alcohol, tea, and coffee is also an important factor.

The "lithemia" of the English school is identical with the "arthritism" of its Gallic neighbors. The Germans had been slow to accept the teachings of either country until Czerny in 1905 published his hypothesis of the "exudative" diathesis. This is supposed to account for many forms of illness during early life, such as infantile atrophy, eczema, pruritus, disturbances of sleep, pharyngitis, bronchitis, asthma, blepharitis, enlarged glands, and hypertrophied tonsils and adenoids. The primary cause of this diathesis is supposed to be a congenital defect chiefly in those tissues that regulate the metabolism of water. The important points in the treatment are the avoidance of overfeeding and, after the second year of life, the avoidance of an excessive vegetable diet. According to Czerny's latest conception the disturbance of the purin metabolism occurring in gout has nothing in common with arthritism.

In a recent monograph on this subject* Professor Wilhelm Stoeltzner of Halle a. S. points out that none of the above diatheses suggests the important organic cause responsible for its evolution. He accordingly proposes the new term "oxypathy," which he believes has a more general significance than any of the terms arthritism, lithemia, and exudative diathesis, each of which connotes some local manifestation of a constitutional disorder. Arthritism emphasizes the tendency to joint involvement, lithemia brings into focus the gouty element, while the exudative diathesis refers mostly to the manifestations occurring in the skin and mucous membranes. It is necessary to go deeper than any of these local pathological tendencies in order to seek the fundamental factor responsible for the host of disorders included in all of the above mentioned diatheses. It is this basic constitutional disturbance which is connoted by the word "oxypathy." The nature of this disturbance consists in an alimentary or constitutional insufficiency of the power to eliminate from the body unoxidizable acids, which harm the organism by uniting with the fixed alkalies of the tissues.

The conception of oxypathy is brought forward in an effort to explain many otherwise puzzling conditions of infancy and childhood. It also suggests new problems in the investigation of the pathology of metabolism. Chief of these are comparative researches into the question whether the alkali-metabolism in oxypathic individuals differs from the normal, either when a period of diet rich in alkalies is followed by one rich in acids, or when a period of acid diet is followed by one containing an excess of alkalies. The clinical expression of oxypathy is practically the same as that described under arthritism. In infancy its most frequent manifestation is the athrepsia of artificially fed infants. The oxypathic diathesis also prepares the soil for other diseases, while the infections occurring in these cases run a particularly unfavorable course.

Stoeltzner characterizes the marantic condition resulting in many infants who are artificially fed as oxypathic atrophy. This is attributed to a chronic alimentary phosphoric acid poisoning, three causes of which are considered: First, a diet rich in both calcium phosphate and fat, through the interaction of these substances in the intestine, sets free phosporic acid. Second, a contributing factor is seen in an accompanying florid rachitis, which, with a diet containing milk rich in fat, favors the liberation of free phosphoric acid. The third factor is a frequently hereditary oxypathic disposition, an individually abnormal acid tolerance. The excess of calcium and phosphoric acid which is found in cow's milk when this is compared with human milk is regarded as responsible for the inability of these infants to thrive. Accordingly the addition of sodium citrate to cow's milk, by binding the calcium and phosphoric acid, removes the disturbing factor in metabolism. Thus the good effects of citrated milk in infant feeding receive an explanation which is quite different from that generally accepted.

*"Oxypathie," von Prof. Dr. Wilhelm Stoeltzner. Berlin: S. Karger, 1911.

It is impossible in this place to more than allude to the subjects that Stoeltzner discusses in relation to oxypathy. These are rachitis, eczema, scrofulosis, the question of familial occurrence, and the incidence of this condition in older children. Although this observer does not clearly indicate the actual mechanism that underlies the evolution of the oxypathic diathesis, this is briefly summed up as a chronic alimentary phosphoric acid poisoning.

In the treatment of this condition, in addition to exercise and the avoidance of alcohol, it is noted that the most important factor is an exclusive or a preponderating vegetable diet. The antioxypathic effect of plant food depends on its abundance in fixed alkali. The cereals and nuts do not possess this property, as they contain acid salts. The vegetables valuable for this purpose are salads, turnips, melons, tomatoes, potatoes, and fruits. The fixed alkalies contained in these are united with organic acids which in the body are oxidized into carbon dioxide. The importance of sodium citrate as a medicament is emphasized, the efficacy of this drug being particularly marked in the treatment of infantile eczema.

This brief review of Stoeltzner's strikingly simple explanation of many pathological manifestations of early life has brought out merely the conclusions of this observer and has omitted the wealth of details which he cites from his extensive clinical experience. His hypothesis, if it cannot be accepted as proven, is, at any rate, an ingenious one.

METASTATIC GONORRHEIC CONJUNCTIVITIS.

Direct transmission of gonorrhea from the urethra to the eye, as well as true metastasis of the disease to both deeper and superficial structures of that organ, has been known for years to the laity, to say nothing of the practitioner. Many a layman believes that he is able to tell from the patient's eye that he has gonorrhea. Leaving out of account all possibility of direct transmission, it must be admitted that the victim of acute gonorrhea often exhibits a peculiarity of the eye which is difficult to analyze. Doubtless the specialist who sees hundreds of cases, most of which are not first cases, can see no general peculiarity of aspect of the eye in his material. It must be conceded, however, that primary gonorrhea is a severe affection, and it is not surprising that a patient with such a disease should show its effects in so sensitive an organ as the eye. The conjunctivæ are often slightly injected, but otherwise it is hardly possible to detect actual lesions. This participation of the eye may be explained sufficiently by the prolonged wakefulness, the painful erections, painful micturition, and injections, with oftentimes the superaddition of a guilty expression due to the fear that the patient's secret is surmised. With repeated attacks of gonorrhea all these disturbing elements vanish and there is nothing present of such severity as to disturb the eye.

Recently a most interesting association has been discussed which may throw some light on the gonorrheic eye as conceived of by the laity. In the *Berliner klinische Wochenschrift*, December 26, 1910, Ruschc describes in detail a new evidence of relationship between the conjunctiva and gonorrhea. The condition described is very simple. A patient with acute gonorrhea of the urethra or elsewhere develops a mild, short-lived conjunctivitis. The bacillus found may be any one of the ordinary exciters of conjunctivitis—the Morax-Axenfeld, Koch-Weeks, pneumococcus, etc. Quite characteristic is the mildness of the affection. The question must at once be asked, "how do we know that this affection represents a metastasis of gonorrhea?" The mere presence of gonorrheal urethritis may not be held sufficient. We may have to exclude the possibility of contact. This may be readily excluded; so that then it will be necessary to seek for other metastases. According to the author any evidence of implication of the joints, tendons, etc., will complete the diagnosis. Another valuable point is this, that after recovery from the first attack of conjunctivitis we may see a relapse with involvement of the cornea or iris or both. It must be remembered that in none of such cases do gonococci appear in evidence. We must, therefore, feel assured that the damage to the eye in all such cases must be due to gonotoxins.

INSANE IN NEW YORK STATE.

The twenty-first annual report of the New York State Commission in Lunacy for 1908-1909 has been issued recently and provides some interesting reading. The report deals with the statistics of the insane and supplies the information that on September 30, 1909, the number of registered insane in the State of New York in institutions under the supervision of the State Commission in Lunacy was 31,541, of which number 15,107 were males and 16,433 were females. The number of patients to each 100,000 of the population of the State in 1909 was 348.9 among males, 375.5 among females, and 362.3 in the total population, or a ratio of one insane male to each 287 males, one insane female to each 266 females, and one insane of either sex to each 276 of the general population. Of the psychoses, dementia precox predominated among the total first admissions; general paresis was second, senile insanity was third, and alcoholic psychoses were fourth. The largest absolute number of first admissions was between the ages of 25 and 30, with numbers nearly as large in each of the five-year periods from 20 to 40 years of age. As to the nativity of the patients in 1909, 44.7 per cent. of the male and 48.3 per cent. of the female first admissions were of foreign birth. The most marked difference between the distribution among the several forms of mental disorder of first admissions of native birth and that of first admissions of foreign birth was the excessively high proportion among Irish first admissions of alcoholic and senile psychoses, the great preponderance of senile insanity among the Germans, and the preponderance of dementia precox among the Russians, Italians, and Austrians.

Statistical studies of the etiological factors assigned in the first admissions during the year end-

ing September 30, 1909, have been considered only on two issues, that of alcohol and that of heredity. Alcoholic habits were recorded in 45.7 per cent. of the male and in 15.7 per cent. of the female first admissions, or in 32 per cent. of the total first admissions. As for heredity, its influence in the causation of insanity was traced in 61 per cent. of the total first admissions, but of family history it was found impossible to obtain dependable accounts, positive or negative, in 23 per cent. of the total number of cases reviewed.

One-fourth of the deaths occurring during the year 1909 were due to diseases of the nervous system, the most prominent in this group being general paralysis of the insane. The next most prominent cause of death was tuberculosis, and over 55 per cent. of the total deaths due to tuberculosis were among cases of dementia precox and over two-thirds of those due to cerebral hemorrhage and apoplexy were cases of psychosis with brain or nervous diseases, cases of dementia precox, or of old age. The report is well worth a careful study.

UNITY IN HEALTH WORK.

Dr. Eugene H. Porter, New York State Commissioner of Health, in an address delivered before the Conference of Mayors at Schenectady, on June 24 last, took as his subject unity in health work. In the course of his address the speaker referred in scathing terms to the bane of politics in municipal management. He pointed out that many if not most large cities of this country were in debt almost up to the legal limit, and that for this reason appropriations for public health purposes were difficult to secure. Consequently, he argued that in order to obtain a satisfactory public health service politics must be driven out of every health department, national, State, and municipal. He also drew attention to the need for educating the public, or rather the rising generation, in sanitary science and public health, and urged that this campaign of education should be commenced in this State.

The speaker specially dwelt upon the necessity for hearty co-operation of both State and local authorities looking to the adequate protection of public water supplies and the proper disposal of sewage. This is manifestly a matter which requires immediate attention in every manufacturing neighborhood. Conditions in New York State are, in so far as the pollution of streams and lakes are concerned, deplorable. Most of the towns of the State are discharging raw sewage into a stream or lake, while the mills and manufacturing establishments are discharging their waste products into the streams. As Dr. Porter pointed out, the solution of the problem is known, but reforms cannot be brought to pass at once, and he believes that the wisest way to solve these questions is by the cordial cooperation of State and local authorities. It is obvious that things cannot go on as they have been going on, and that alterations must be introduced which will tend to conserve the public health. A commencement should be made in this direction with the water pollution question. It is the most important and most urgent.

The Treatment of Duodenal Ulcer.

Surgical treatment of duodenal ulcer has been strongly advocated during recent years, especially by Mr. Moynihan of Leeds, who has written largely on the subject and has appeared to make out a very good case for his form of treatment. Yet the more conservative of the medical profession, indeed the majority, are of the opinion that therapeutic measures and medical treatment generally should be given a fair trial before the knife is brought into use in the instance of those suffering from duodenal ulceration. In the *Medical Press and Circular* of December 14, F. de Haviland Hall has an article in which he concludes from a consideration of three cases that it may be laid down as a demonstrated truth that ulceration of the duodenum attended with profuse, and even recurrent hemorrhage, is amenable to medical treatment. Hall further is of the opinion that it is advisable to treat the first attack on purely medical grounds. In the next place, it is pointed out that though gastrojejunostomy may be successful at the time in relieving the urgent symptoms of duodenal ulceration, it does not prevent the recurrence of hemorrhage, and should there be a recurrence Hall thinks that the patient should be treated medically rather than placed under surgical treatment again. Finally, the conclusion is reached that there are cases of duodenal ulceration, those in which perforation has occurred, in which operative interference is absolutely necessary if life is to be saved. There is, however, a great tendency to recurrence of ulceration in the duodenum, a tendency which purely medical treatment is not always sufficient to overcome. When, therefore, a patient has not improved under medical treatment the question of a resort to gastrojejunostomy must always be considered.

Mental Defects Following the Use of Alcohol.

This is a subject which has been dealt with, and is still being discussed almost *ad nauseam*. However, it is no doubt in the best interests of the general public that the physician should continue to take the keenest interest in all that concerns the use or abuse of alcohol by man. In the *Southern California Practitioner* for December is an article by Dr. James T. Fisher on the alcohol question which contains some interesting matter. Fisher, who is visiting physician to the Los Angeles County Hospital, has excellent opportunities for studying the alcoholic psychoses in all their varieties. Among other phenomena he noticed was that over 70 per cent. of the patients examined had a neuropathic heredity. Another point to which attention is drawn is that the delusions of alcoholic paranoics all hinge on the sexual organs. As to the periodicity of alcoholic or drug excesses Fisher thinks that such periodicity should not alone class it among the cyclic insanities, for in his opinion periodicity is not an essential feature, as a dipsomaniac may have only one or two attacks in a lifetime. This seems to be rather an extreme conception of dipsomania, but Fisher is firmly convinced that periodical drinking to excess is a disease, and this being so it is, he maintains, by no means impossible to think that an individual, even one burdened by an unstable heredity, may have but two attacks in a lifetime.

News of the Week.

Scholarship in Ophthalmology.—Announcement is made of the foundation of a scholarship in ophthalmology in Columbia University, New York. A fund amounting to $18,000, to be known as "The Doctor Abram Dubois Memorial Fund," has been presented to the university by the sons and daughter of Dr. Dubois. The scholarship is open to graduates of the College of Physicians, who have satisfactorily completed a term of service in an eye hospital, and who have given evidence of serious intention of pursuing ophthalmology as a specialty. The holder of the scholarship is expected to devote himself to post-graduate studies, preferably of a scientific character, connected with ophthalmology in foreign and American universities. The income will be about $700. The bestowal of the scholarship is in the hands of a committee consisting of the Dean and the Professor of Ophthalmology of the College of Physicians and Surgeons, and Dr. Edward L. Partridge.

Woman Ambulance Surgeon.—The Williamsburg Hospital, Brooklyn, New York, has another woman ambulance surgeon, Dr. Elizabeth Bruyn, a graduate of Cornell University Medical College in the class of 1910. Dr. Bruyn began her service on the ambulance on January 16. She is the second woman to serve in that capacity in the hospital.

Benefits of Open-Air School.—The report of the year's work at the Elizabeth McCormick Open-Air School in Chicago, issued recently, sets forth the gratifying improvement obtained in the physical condition of the children, a net average gain of four pounds being noted, and also shows that the children are able to do good school work in the strange environment. Of the thirty children in regular attendance from January to July, 1910, twenty-three completed the work of one grade, three completed two grades, and one completed three grades.

Fire Department Hospital.—A new operating-room was opened at Fire Headquarters in New York on January 15, with a staff of six surgeons under Dr. Herman L. Reis, to look after the injured firemen of Manhattan and the Bronx. Last year there were 806 cases of illness and 266 cases of injury in the department, many of the patients having to be treated by outside surgeons owing to the lack of proper appliances.

Aid for Famine Victims.—The American Red Cross on January 16 sent $5,000 to China for the relief of the sufferers from the famine. This makes a total of $10,000 so far sent by the Red Cross.

Diphtheria at Harlem Hospital.—Three nurses and one interne at the Harlem Hospital, New York, have been ill with diphtheria contracted from a child who developed the disease shortly after admission to the hospital.

The Kaiser an M.D.—Kaiser Wilhelm of Germany is soon to add the degree of Doctor of Medicine to his already somewhat numerous distinctions. The degree has been offered by the University of Prague, and has been accepted. It will be conferred with great ceremony.

Infirmaries Merge.—The Long Island Throat Hospital and Eye Infirmary, which has been located for a number of years at 55 Willoughby street, Brooklyn, has been merged with the Brooklyn Eye and Ear Infirmary in Livingston street. The value of the property thus transferred is placed at about $15,000.

Proposed State Cancer Hospital.—A bill recently introduced into the New York Legislature provides for the appropriation of $65,000 for the erection of a hospital adjoining the State Cancer Laboratory in Buffalo, for the treatment of patients suffering from the disease. The bill names as trustees of the proposed institution Dr. Roswell W. Park, William H. Gratwick, and Dr. Charles Cary of Buffalo, John G. Milburn and Charles S. Fairchild of New York, and Frederick S. Stevens of Albany. It is understood that the land for the building will be donated to the State.

Asylum or Hospital.—A bill will shortly be introduced into the Michigan State Legislature asking that all the State asylums for the treatment of insane patients be re-named State Hospitals. A committee representing every asylum in the State has protested against the use of the words "insane asylum."

Post-Graduate Dinner.—Under the auspices of the directors and faculty of the New York Post-Graduate Medical School a dinner was given at Delmonico's on January 19, about 250 graduates and guests being present. Among the speakers and guests of honor were Drs. William H. Welch and W. S. Thayer of Johns Hopkins Medical School, Surgeon-General Charles F. Stokes, U. S. N.; Surgeon-General Torney, Dr. Daniel Lewis, and Dr. E. B. Dench.

Dr. S. Weir Mitchell has resigned from the Board of Trustees of the University of Pennsylvania.

Dr. Gwillym G. Davis, associate professor of applied anatomy, has been elected professor of orthopedic surgery in the medical department of the University of Pennsylvania, in succession to the late Dr. De Forest Willard.

Smallpox in Philadelphia.—One death from "black" smallpox in Philadelphia has resulted in widespread vaccination and quarantine of the exposed district. The victim, a boy of three years, died on January 20 after two weeks' illness. The health authorities trace the infection to a boy who arrived in Philadelphia from Bremen on December 17. He was taken ill on the voyage and was sent to the Philadelphia General Hospital, supposedly suffering from measles. Five days later he died. In the hospital at the same time was the older brother of the little Philadelphia boy, who later developed the disease, and it is thought that the immigrant child probably died of the hemorrhagic form of smallpox. An epidemic of the same disease occurred in Philadelphia in 1871.

Increase in Cholera.—The epidemic of cholera in Madeira is reported to be on the increase. Up to January 15 1,646 cases of the disease and 535 deaths had occurred.

Plague in China.—The first death from bubonic plague in Pekin since the outbreak of the present epidemic occurred on January 20. Throughout Northern China and Manchuria the situation is very grave, and hundreds of deaths have been reported. The ignorance of the people is largely responsible for the spread of the disease, since they oppose the burning of bodies, or even of infected houses, and dispose of their dead by throwing them into rivers, or leave the bodies in the houses or street. The Chinese officials have to a large extent

surrendered command to the missionary physicians, and the Government, realizing the very dangerous nature of the service, is insuring each foreign volunteer for $20,000. In Harbin the Russians are taking active measures to protect their own section of the city, and are dealing drastically with the Chinese resident there, with the result that the Chinese newspapers are expressing their resentment by bringing serious charges of persecution and burial alive. A censorship of the press has been suggested, as such charges make the tasks of the health officers much more difficult.

The Child's Welfare Exhibit was opened at the 71st Regiment Armory, New York, on January 18. Daily sessions will be held until February 12.

Charitable Bequests.—By the will of the late Mrs. Emilie H. Moir of New York, who died on December 23, a large number of charitable institutions receive bequests. Among them are the New York Eye and Ear Infirmary, $20,000; the Lying-In Hospital, $10,000; the Hospital for Scarlet Fever and Diphtheria Patients, $10,000; the Babies' Hospital, $10,000; the Northern Dispensary, $5,000, and the Nursery and Child's Hospital, $5,000. The Presbyterian Hospital receives $20,000 and one-fourth of the residue of the estate, this latter share being estimated at about $200,000.

The Eastern Maine General Hospital of Bangor receives $4,000 for the endowment of a child's cot by the will of the late Mrs. Gardner B. Perry of Boston, who died recently.

By the will of the late Miss Octavia W. Bates, who died in Baltimore a short time ago, the Harper Hospital of Detroit, Mich., receives a bequest of $30,000 to be used for the endowment of six beds in memory of members of the testator's family.

The Children's Seashore Home at Atlantic City, N. J., receives a bequest of 500,000 francs under the will of the late Georges Bertin of Paris.

A bequest amounting to about $5,500 is left to the Servants of Relief for St. Rose's Free Home for Incurable Cancer in Cherry street, New York.

Quarantine Lifted.—The shipping quarantine against Constantinople was abolished on January 21, and clean bills of health will be issued. Since the outbreak of cholera last September there have been 1,318 cases with 793 deaths.

In Memory of Dr. John Morgan.—A committee consisting of Dr. Swithin Chandler, Dr. Edgar F. Smith, Provost; Dr. S. Weir Mitchell, Dr. Wm. Pepper, and Dr. Clarence P. Franklin, has been appointed to identify the grave of Dr. John Morgan, who founded the University of Pennsylvania in the year 1765, and appropriately to mark the spot with a suitable memorial and also to raise sufficient funds for the erection of a monument to the memory of Dr. Morgan.

Philadelphia County Medical Society.—At a stated meeting held January 18 the following officers were elected for the ensuing year: *President*, Dr. Christian B. Longenecker; *First Vice-President*, Dr. Levi J. Hammond; *Associate Vice-Presidents*, Drs. Wm. N. Bradley, Thomas R. Currie, Henry D. Jump, Frank Embrey, and Aaron Bray; *Secretary*, Dr. Wm. S. Wray; *Assistant Secretary*, Dr. Herbert B. Carpenter; *Treasurer*, Dr. Collier L. Bower; *Censor*, Dr. Lewis H. Adler, Jr.; *Directors*, Drs. Herman B. Allyn, G. Morton Illman, and Edward A. Shumway.

American Guild of St. Luke.—The next meeting of this society of physicians will be held on Thursday, February 2, at the Catholic Club, No. 120 West 59th street. The subject for general discussion will be "Alcoholism in its Relations to Crime and Heredity." Dr. Charles E. Nammack is the president, and Dr. James J. Walsh the secretary, of the Guild.

The Late Dr. Alexander.—At a recent meeting of the faculty of the Cornell University Medical College the following minute was adopted: "The Faculty record with deep sorrow the death of their associate, Dr. Samuel Alexander, which took place after a brief illness in his fifty-second year. Dr. Alexander was graduated from Princeton University in 1879, and three years later received the degree of M. A. from the same institution. After completion of his medical studies at the Bellevue Hospital Medical College he became an interne in Bellevue Hospital where he held a practically continuous service until the time of his death, passing through successive grades of advancement from house surgeon to attending surgeon. Dr. Alexander early devoted special attention to the study of genitourinary surgery, and was made professor of this branch of medicine in 1889 in the Bellevue Hospital Medical College, a position which he resigned in 1900 to occupy a similar chair in the Cornell University Medical College. He attained marked distinction in his special department of surgery, being not only a skillful diagnostician and operator, but devoting much time to the development of pathological research in its application to the treatment of genitourinary diseases. His high standing in the profession which he honored is attested by his election to many representative societies, both in this country and abroad, including the New York Surgical Society, the Practitioners' Society of New York, the International Surgical Society, the French Society of Surgery and the International Urological Society. Before the latter association he had been invited to deliver the address of honor during the coming summer. He contributed many valuable scientific papers to the literature of his special department of surgery. Dr. Alexander's interest in Princeton led him to do much for that institution and he remained one of its most active and enthusiastic Alumni. His kindly spirit, genial good fellowship and ability as a fluent and witty speaker endeared him to a host of friends, and in the Faculty of this college he was not only admired for his high high standard of scientific attainment, but for the wisdom of his counsel in many questions of organization and development. It is directed that this record be spread upon the minutes of the Faculty as a tribute to Dr. Alexander's character and worth, and that a copy be transmitted to his family." (Signed) W. Gilman Thompson, John A. Hartwell, Committee of the Faculty.

The Late Dr. Lustgarten.—The following resolutions were adopted at a meeting of the Medical Board of Mount Sinai Hospital, held January 23: "The members of the Medical Board of Mount Sinai Hospital have heard with profound regret of the death of their colleague, Dr. Sigmund Lustgarten. In his death Mount Sinai Hospital loses one of its most faithful medical officers, distinguished by preeminence in his especial field of work, by unusual clinical ability, and by devotion to the highest ideals of the profession. His genial personality had endeared him to all his coworkers in the hospital, each one of whom feels in his death a sense of personal loss. *Resolved*, That the foregoing sentiments be spread upon the minutes of the Medical Board, that they be published in

the medical press of this city, and that a copy of the same be sent to his widow. *Resolved* also, That the Medical Board attend the funeral in a body." (Signed) A. Jacobi, M.D., *Chairman*, M. Manges, M.D., *Secretary*.

Obituary Notes.—Dr. William J. Furness of New York, a graduate of the University of Michigan Department of Medicine and Surgery, Ann Arbor, in 1891, a member of the New York State and County Medical Societies, the American Medico-Physiological Association, and the Harlem Medical Association, visiting surgeon to St. Joseph's Hospital and Harlem Hospital Out-Patient Department, gynecologist to the Calvary Methodist Episcopal Dispensary, and assistant gynecologist to the New York Polyclinic and Woman's Hospital, was instantly killed on January 17 when the automobile which he was about to drive from the garage was accidentally backed down an elevator shaft. Dr. Furness was forty years of age.

Dr. Sigmund Lustgarten died on Sunday last, at his home in this city, at the age of fifty-three years. He was born in Vienna and was graduated in medicine from the University in that city in 1881. For a number of years he was assistant to Kaposi in the dermatological clinic at the University of Vienna. In 1889 he came to New York. He was dermatologist to Mount Sinai Hospital and consulting dermatologist to the Montefiore Home and the Hebrew Orphan Asylum. He was a member of the medical societies of the State and County of New York, of the American Dermatological Society, the New York Dermatological Society, and the German Medical Society.

Dr. Charles J. Kipp of Newark, N. J., died at his home of pneumonia, on January 13, aged 72 years. Dr. Kipp was born in Hanover, Germany, but received his medical education at the College of Physicians and Surgeons, New York, from which he was graduated in 1861. During the Civil War he served first as surgeon to the Fifth Regiment, N. G. N. Y., and later was assigned to the Third Battalion, New York Artillery. In 1864 he was made surgeon of United States Volunteers, and the following year was brevetted lieutenant-colonel. In 1869 he began to practise in Newark, organizing the first eye and ear clinic at St. Michael's Hospital in 1870. He served as president of the Essex County Medical Society in 1880, and of the New Jersey State Medical Society in 1886. From 1901 to 1906 he was president of the New Jersey State Tuberculosis Sanatorium, and was president of the American Ophthalmological Society in 1907, of the American Otological Society in 1908, and vice-president of the American Medical Association in 1909. At the time of his death he was also a member of the Ophthalmological Society of Heidelberg, Germany, the New York Academy of Medicine, and the New York Pathological Society. He was surgeon to the Newark Eye and Ear Infirmary, and consulting surgeon to St. Barnabas', the German, Bayonne, Mountainside, and Somerset Hospitals, and chief of the eye and ear infirmary of the Newark City Hospital. His contributions to medical literature were numerous.

Dr. John A. Hemsteger of Chicago, Ill., a graduate of the University of Berlin, Germany, in 1879, and of the Chicago Homeopathic Medical College in 1890, a member of the American Institute of Homeopathy and of the Illinois State and Chicago Homeopathic Medical Societies, died suddenly, on January 5, aged 56 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE CAMPAIGN AGAINST TUBERCULOSIS—VIEWS OF MEDICAL OFFICERS OF HEALTH—VALUE OF SANATORIUM AND DISPENSARY TREATMENT—LIQUID AIR AND CARBON DIOXIDE SNOW—ITEMS.

London, January 6, 1911.

The medical officers of health have of late been discussing the subject of tuberculosis—naturally for the most part from a preventive point of view with reference to the question of municipal duty. It is held generally that every sanitary authority should make an effort to control consumption, and notification is mostly recommended as a first step toward that goal. Dr. Wm. Robertson of Leith stated at the meeting of the Health Officers' Society last month that voluntary notification had been tried at Leith since 1904, and in Scotland the authorities could impose compulsion if they satisfied the Government Board that they would follow it up with active steps. He advocated the removal of cases which were unsuitably housed, or where precautions could not be enforced. They had at first twelve beds in the Leith Hospital, but had to increase to twenty. Advanced cases were not admitted. In some instances contacts had been taken in from a house where there was an advanced case. The pale children of consumptives were placed in the open-air ward. Visitation to houses after the return of contacts was carried out to insure that the open-air plan was continued.

In the discussion that followed compulsory notification was strongly advocated, but it was admitted that it must not be too rigorously enforced. The importance of sanitary surroundings was put forward by some speakers, and it was pointed out that the poor-law authorities had heretofore made no effort to improve the surroundings of those to whom they gave outdoor relief. The establishment of dispensaries for treatment by tuberculin was also recommended by two or three speakers, and Dr. Wilkinson, who opened one in South London some months ago, gave an account of his proceedings.

The health officer of Portsmouth has, I hear, advised his sanitary authority to make a trial of tuberculin treatment in a dispensary before going to the great expense of erecting a sanatorium for open-air treatment. In his report and also in the press he has compared the two methods, and is evidently strongly impressed by the successes reported by the directors of dispensaries. The two methods are to a great extent opposed to each other, and yet not in the way too often supposed. Indeed, in Germany they have been employed together, and Professor Möller says "cures" have been obtained within three months by tuberculin combined with sanatorium residence. But it is not as a supplemental treatment that tuberculin is being tried in dispensaries opened for that purpose. It is regarded as a complete treatment, and in many respects as a contrast with the sanatorium.

Few observers fail to notice that no little disappointment has followed the building of sanatoriums. Exaggerated expectations were doubtless largely indulged in at first, and the warnings of cautious practitioners neglected. Many cases were arrested and loudly claimed as cures. Later the advocates proclaimed the necessity of early resort to and prolonged residence in the sanatorium, and here we see

the two most important difficulties, and in the majority of cases they cannot be overcome. Well-to-do patients can afford to leave their homes for a prolonged period. Not so the working classes. These, indeed, do not often get their disease diagnosed in the early stage. Most practitioners will testify that they keep at work until the first stage has passed. They are not then "suitable cases," and even if admitted they cannot afford to remain long enough away from their families. They return, therefore, too soon, and constitute the relapses of which we hear. These are some of the reasons which have induced a number of practical men to ask whether there might not be more hope in tuberculin—whether it had been sufficiently tested? A positive reply to this question has been given by many in Germany, and seems to be gaining concurrence in this country. It is the most hopeful, so say the most enthusiastic few who are for exploiting the plan of dispensaries where patients can attend at proper intervals without giving up work or leaving a family without provision. The money difficulty does not arise in this case, and if the treatment proved as efficient as represented in some quarters the gain would be incalculable. In this plan, as in every other, the importance of early treatment is obvious, but the impediments of poverty do not prevent a trial as soon as a diagnosis is made.

The Association of Medical Women has been discussing the question. Dr. Hilda Clark, who has opened a dispensary in Somerset, described her plan. The patients attended twice a week, were given advice as to their personal hygiene, their weight and temperature taken. They were also visited in their homes and advised on sanitary matters. Koch's old tuberculin (bovine) was used in increasing doses; later the human preparation. The patients generally continued at work and none were the worse. At first some compalined of abdominal pain after the injections. Dr. Jane Walker had tried the plan, but could not report benefit, and thought a long time must elapse before the effect could be judged. Dr. Esther Canling also could say little for the plan. She had tried it in an advanced case, but the patient got worse; in a laryngeal case without improvement, and in a very early pulmonary case which did not do so well as under other treatment.

Drs. Taylor and McKenna stated at the Liverpool Institute their experience with liquid air and carbon dioxide snow during about three years. Liquid air was two and one-half times colder than the snow, and was easily applied on cotton wool, twisted around a cane, but it was costly and evaporated rapidly. But it must not be applied as long as the carbon dioxide snow, which had the advantage of being cheap and the pencils easily made. Neither remedy was very painful except over superficial nerves, or the teeth, or ears, or a bone. Refrigeration should not be applied to old patients or those who were broken down or had nephritis or arteriosclerosis.

In the new year's list of honors Dr. Jameson, late premier of Cape Colony, has a baronetcy, and the following medical men are given a knighthood: Dr. Donkin, Mr. Eve, Dr. D. Ferrier, Dr. Geo. Newman, Dr. J. M. Redmond, Hon. J. H. M. Beck, Lieut-Col. D. Semple. The Kaiser-i-Hind Medal is conferred on Lieut.-Col. Dr. Henry Smith, I. M. S., and Major T. W. Dr. Irvine. Drs. Jameson and Beck, above named, are honored as leaders in South Africa and in commemoration of the Union.

The League of Mercy's contribution for the year 1910 to King Edward's Hospital Fund amounts to £18,000.

The pharmacists propose appealing to the Privy Council and representing that there are grave dangers in dispensing by doctors and in public dispensaries by those who have not the license of the pharmaceutical society. They seem to forget that their own privileges so far have been taken from those of the doctors. Having so much they ask for more.

The real abuse that exists is that these druggists are guilty of "counter prescribing." That is what is a public danger and should be put down, as should, too, the sale of quack medicines.

Col. F. Howard, late A. M. S., has died at Bournemouth. He took his M.D. St. Andrews in 1862, and joined the army the next year. He saw service in the Afghan War, 1878, and was awarded the medal. In the Egypt Expedition, 1882, he received the medal and bronze star. He retired in 1892, but was reemployed at the War Office during the South African War. He wrote the "Hand-book of Medical Organizations of Foreign Armies."

Acute Poliomyeloencephalitis (Infantile Paralysis). J. L. Morse.
The Treatment of Acute Poliomyelitis. W. E. Paul.
A Review of Sanitation in Panama. F. P. McCarthy.
Some of the More Important Diseases of the Upper Abdomen That May Require Surgical Intervention. J. W. Keefe.
Mongolian Idiocy. W. N. Bullard.

Acute Poliomyeloencephalitis.—J. L. Morse states that this is due to an ultramicroscopic organism, belonging to the class of the filterable viruses in which belong the organism of foot and mouth disease and those of a number of other diseases of animals. He discusses the modes of infection and of escape of the virus, the contagiousness, methods of contagion, period of incubation, protection against contagion, the pathology, symptomatology, Wickman's classification, diagnosis, prognosis, and treatment. It is noted that hexamethylenamin can do no good after the appearance of the paralysis, because the harm has then already been done. It is possible, perhaps probable, that it may do good if it is given before the appearance of the paralysis. It certainly should be given to all children who may possibly have been exposed to the disease. Since there is nothing characteristic about the early symptoms of acute poliomyeloencephalitis, it would be necessary, in order to give it in time, and in order not to miss any of the cases, to give it to every sick child all summer, which certainly does not seem reasonable.

Treatment of Acute Poliomyelitis.—W. E. Paul calls attention to the fact that wide as is the range of pathological damage to nerve structures in poliomyelitis, it is in only one group of neurons that the harm done calls for therapeutic measures during convalescence and the later stages of the disease. The meninges, the sensory columns, perchance, every columnar tract of the cord, the peripheral nerves, may all be involved as well as the anterior cornual cells and higher motor nuclei, but treatment has to be considered in a practical way only in the conservation of these motor neurons.

Sanitation in Panama.—F. P. McCarthy states that the mortality rate shows a definite reduction from year to year. In 1904, when the population was small, there was a death rate per thousand of 52; the following year a somewhat higher rate, about 65 per thousand; and in 1908 it had dropped to 24 per thousand; last year, 22 per thousand, corresponding favorably with the mortality in any of the large American cities. A constant and absolute

medical supervision has brought about these remarkable results in the health conditions on the Isthmus, and eternal vigilance is necessary to preserve such conditions.

Surgery in Diseases of Upper Abdomen.—J. W. Keefe concludes with the following schematic summary: Ulcer of the stomach—Hyperacidity, hematemesis, pain directly after eating. Ulcer of the duodenum—Blood in the stools. The pain which comes on three or four hours after eating does not radiate to the back. It is localized just below the gall bladder. Gall-bladder infection—Chills, fever, pain over gall bladder, intermittent in character, nausea, and vomiting. Pancreas—Sudden onset, marked prostration, dyspnea, lividity, cyanosis, intense pain. Upon opening the abdomen beef-both-like serum. Areas of fat necrosis. Cancer of the stomach—Vomitus resembles coffee grounds. Absence of HCl. Growth may be palpated. Cachexia. Send a short history of your patient when sending him to a hospital. Beware of those cases called chronic nervous dyspepsia, *et cetera*. Look for some definite pathology of organic disease. Remember that infection of the bile tract always precedes the formation of gallstones.

Mongolian Idiocy.—W. N. Bullard describes the typical physical characters and distinguishing peculiarities of these defectives as follows: 1. Mongolian idiots almost universally show signs of general arrested development. They are small and symmetrically developed but appear, especially during the period of growth, like children two or more years younger than they actually are. 2. Another symptom is brachycephaly. The cranium is in these patients not only small and often so disproportionately small as to be technically microcephalic, but it is brachycephalic; that is, the transverse diameter is excessively large in proportion to the shortened anteroposterior diameter. 3. The occiput is apt to be steep or flat. 4. The face is usually dull or stupid in expression. 5. One of the most obvious and characteristic signs of this condition is the slanting direction of the eyes. This is almost a pathognomonic sign, yet it is said to occur exceptionally in other forms of idiocy and even occasionally in the otherwise normal Caucasian. Strabismus is not rare, but is not distinctive. Nystagmus is said to be often present in the first six months of extrauterine life. The face is often broadened and flattened; the nose broad, its bridge sunken, and the nostrils facing upward, thus resembling the face of the cretin or cretinoid idiot. In many cases, however, this facial form is not present. The skin of the face is delicate, thin, easily roughened. The mucous membranes are extremely sensitive and liable to irritations and inflammations, particularly blepharitis and nasal catarrh. Almost pathognomonic also is the appearance of the tongue, which shows deep, sharp-edged, more or less transverse fissures in its anterior and middle portions. These do not appear at birth; the earliest date of appearance noted seems to have been at 22 months. Hypertrophy of the fungiform papillæ is reported. Muir states that palatal deformities occur in 65 per cent. The teeth are apt to be irregular in size, shape, and position. The hands are short, flat, and stumpy. There is said to be at times a disproportionate shortness of the thumb and of the fifth finger. Much has been written about the peculiar inward curve of the fifth finger, but this is not always present and, moreover, has been found to occur in other varieties of defectives and in normal persons, and is not characteristic.

A Few Neglected Points Concerning the Treatment of Fractures with Special Reference to Those of the Leg. C. Beck.
How Pure Milk Cultures of Lactic Ferments May be Obtained. F. S. Mason.
Stereoscopic Photography with a Single Camera. Some Points in Optics and Physiology. W. G. Elmer.
Grams in Three Dimensions. A Preliminary Report. M. Girsdansky.
The Identification of the Tubercle Bacillus by Means of Antiformin. D. Felberbaum.
Studies in Diet, Nutrition, and Growth in Childhood. E. M. Sill.
The Heart in Lobar Pneumonia and Its Treatment. E. E. Cornwall.
A Case of Toxic Hematoporphyrinuria (Saffron) Complicating Septic Perforation of the Uterus.

Treatment of Fractures.—C. Beck states that while an attitude of indifference toward the operative treatment of fractures that show a tendency to considerable displacement is to be condemned, nevertheless the *furor operativus* which characterizes some work of the more strenuous surgeons deserves restriction. As long as it is possible to reduce a fracture, especially a nondisplaced one, by a bloodless method, it is unjustifiable to change a subcutaneous fracture into an open one when not necessary. As the basis of proper therapeutic action stands a correct diagnosis, in other words, the foundation of treatment consists in the recognition of the correct anatomical details of the fractured area. The character of the treatment is therefore anatomical, the exact apposition of the bone fragments being the essential therapeusis. In fact, the treatment of the more or less injured soft tissues around the fragments is practically of little importance, the correct apposition of the bone ends being the all-important factor, and the sequelæ of too long continued immobilization will be avoided and suppressed by early, careful motion and methodical massage, often combined with the application of a removable splint of plaster of paris. Surgical instinct, educated by Röntgen ray observation, will tell which method is the best to pursue at first, giving the individual case an exploratory character. In some cases the opinion may not be furnished before the elapse of several weeks, when continued displacement may urge the necessity of a chisel operation, after some milder means which were tried at first have proved to be in vain. As the best bloodless means of reposition in displacement the author regards the old extension method of Gurdon Buck, which has lately been greatly improved by Bardenheuer. It is sometimes very practicable in cases of much displacement, but not as reliable as wiring.

Cultures of Lactic Acid Bacilli.—F. S. Mason describes the technique for making milk cultures of the *Streptobacillus lebenis* and *Streptococcus lebenis*.

Stereoscopic Photography.—W. G Elmer describes the following method of making stereoscopic pictures with a single camera. The camera is carefully centered on the object and the picture taken. The camera is shifted three inches to one side—about 2½ inches if the object is very near—carefully centered on the object and the second picture taken. There are now produced two views of the object by converging the axes of the camera upon it in the same manner that the axes of the eyes converge upon a near object. The optical illusion is therefore more perfect than when the axes are parallel, as in the use of a stereoscopic camera.

Röntgenograms in Three Dimensions.—M. Girsdansky describes his new method of *x*-ray stereoscopy as follows: Assuming that the object is of such a size as to enable one to photograph it twice on the same plate, he places the object over one-half of the plate, while the free half of the plate is protected with a sheet of lead, and a picture is taken. The operation is now reversed: The lead is put over the already exposed part; the object is moved over the still unexposed part with the utmost care that it maintains a position as symmetrical as possible to the source of light and to its own former position, and the picture is taken again. When the plate is developed it shows a picture which resembles one taken with an ordinary stereoscopic camera. A print from such plate differs from the commercial stereogram in that it is, in relation to the commercial picture, a transposed one, *i.e.* opposite to the right eye occurs the picture as would

be seen by the left retina, and opposite the left eye occurs the picture as would be seen by the right retina.

Identification of Tubercle Bacillus.—D. Felberbaum concludes that the Ziehl-Neelson method, if carefully carried out, gives such high percentages of positive results that it is sufficient for ordinary routine clinical purposes. The antiformin process is destined to take a permanent place in laboratory methods, inasmuch as it is the best means of concentrating the tubercle bacilli yet advanced, and should be applied to all doubtful cases. To determine the presence of tubercle bacilli in pathological exudate other than sputum it is the best method at our disposal. Antiformin is an exceedingly valuable aid to the bacteriologist in preparing pure cultures or in inoculating guineapigs, making both a much easier and more certain procedure.

Diet in Childhood.—E. M. Sill suggests the following schedule in compiling a suitable diet for both healthy and malnourished children. One-half hour for breakfast, 7 to 8 A. M.: Glass of milk, baked apple, or orange. Cereals: Oatmeal, cracked wheat, farina, hominy, etc., 2 to 3 tablespoonfuls of one of these cereals, with cream and milk. Eggs, 1 to 3, according to the age of the child, either soft boiled, scrambled, poached, or in the form of an omelet; or a lamb chop or fish for variety occasionally. One to three slices of bread, three-eighths of an inch thick, with butter. Ten A. M.: An apple, a banana, a couple of graham crackers, or a small glass of milk. One hour for dinner, 12 to 1 P. M.: Soup, bread, and butter. Meats: Rare steak, rare roast beef, mutton, or chicken (fish may be given once a week). From ⅛ to ¼ of a pound of meat should be given, according to the age and capacity of the child. Baked or boiled potatoes, with butter and salt, or stewed with milk, and a green vegetable, such as spinach, carrots, string beans, green peas, cauliflower, squash, a purée of dried soy beans, or dried peas, may be given three or four times a week at this meal, or baked beans may be given, 1 to 2 tablespoonfuls, and this will in a measure take the place of meat. A glass of milk. Hominy or rice may be given three or four times a week (2 to 3 tablespoonfuls). A simple dessert, such as plain rice pudding, plain bread pudding, custard, blanc mange, ice cream. At 4 P. M.: An apple, peach, or pear may be given if the child is hungry. Half an hour should be taken for supper, at from 6 to 7 P. M.: Bread and butter and a glass of milk, or bread and milk, milk with one of the cereals, bread and butter with jelly, fruit juice or syrup, a bit of cold meat, or omelet, or scrambled eggs.

The Heart in Pneumonia.—E. E. Cornwall concludes that the specific toxin of pneumonia does not seem to be regularly a serious disturber of the heart in the sense that the toxins of diphtheria and influenza are such. Sometimes a severe toxemia, which appears to be a pneumococcus septicemia, is observed in pneumonia, which seriously or fatally poisons the cardiac apparatus or paralyzes the vasomotor center. A constant, and on the whole the most important, cause of heart disturbance in pneumonia seems to be the mechanical obstruction in the lesser circulation caused by the pulmonary consolidation. The prevention of toxemic complications is best effected, pending further developments in serum and vaccine therapy, by maintaining the bodily functions in as high a state of efficiency as possible, particularly the function of the kidneys. From the therapeutic viewpoint a case of pneumonia appears essentially a heart case, in which the problem is to support the heart until the obstruction in the pulmonary circulation has been relieved. Direct support of the heart by stimulation should not be delayed too long in pneumonia; the amount of stimulation should be regulated not only by the requirements of the circulation, but also by the capacity of the heart to respond; and the dangers from overstimulation should be kept in mind.

Hematoporphyrinuria Complicating Septic Perforation of the Uterus.—S. Wiener reports a case of this condition in which, with a grave uterine injury and peritonitis present, it was a difficult matter to say to what extent the drug toxemia contributed to the fatal issue. Yet the profound disturbance of pigment metabolism, the peculiar discoloration of the lips and skin, and the rapid onset of coma would seem to indicate that the immediate cause of death was saffron poisoning and not peritonitis. The patient withstood the shock of the technically easy operation well, and it would be rather unusual for peritonitis to kill so rapidly. However, one must attribute the hematoporphyrinuria to the ingestion of saffron. It has been found heretofore in sulphonal, trional, tetronal, and lead poisoning, and in various diseases. There is no case on record where it was caused by saffron poisoning. Yet Garrod has shown that intestinal hemorrhage may give rise to hematoporphyrin in the urine. In Corvey's case of saffron poisoning the autopsy showed blood in the stomach and intestines. Finally, in Ferraris' case, the urine was reported as "bloody." Whether the hematoporphyrinuria in the author's case was due indirectly to an intestinal hemorrhage or directly to a disturbance of pigment metabolism it was not possible to say.

Gastric and Duodenal Ulcer.—J. N. Hall describes the advantages and disadvantages of medical treatment as follows. The advantages are: Avoidance of immediate operative and anesthetic dangers. Avoidance of chance of occurrence of vicious circle, recurrence of jejunal ulcer, ventral hernia, postoperative adhesions, etc. Against these advantages one should set the following dangers: (1) likelihood of failure of medical treatment; (2) at least an even chance that the patient will relapse if temporarily cured; (3) dangers of development of pyloric stenosis through presence of an active ulcer at that point, or spasm caused by its irritation, or cicatricial stenosis following its healing; (4) danger of hemorrhage or acute perforation; (5) danger of the development of cancer on the base of the ulcer (68 per cent. of the pylori excised by the Mayos for cancer showed origin in an ulcer, while 71 per cent. of those excised under the belief that they were cases of ulcer showed beginning cancerous changes); (6) danger of adhesions, which cripple the action of the stomach, obstruct the gall-passages, produce serious pain, and often require late operation; (7) dangers from a troop of late complications of slowly developing perforation, among which the author has encountered peritonitis, subphrenic abscess, empyema, pyopneumothorax, pneumonia, perforation through the lung, septic pericarditis, mediastinitis, pancreatitis, suppurative processes about the liver and gall-ducts, and general sepsis; (8) development of such a condition of anemia and malnutrition from the crippling of the digestive apparatus as to lead to neurasthenia, hysteria, and various functional nervous diseases, or to pave the way for an easy and often fatal infection by the tubercle bacillus, pneumococcus, influenza bacillus, etc.

Report on Salvarsan.—M. F. Engman, W. H. Mook and J. W. Marchildon report their results in the use of this remedy in sixteen cases of syphilis. They state that except in one case they have seen equally as rapid disappearance of skin manifestations from the use of injections of mercury; but several of the cases they reported seemed to be rebellious to mercury. Reasoning from analogy and knowledge of chemical therapy, a certain per cent. of cases will also, no doubt, prove rebellious to Ehrlich's remedy; but no matter how many may prove rebellious, it has a remarkable effect on the cutaneous manifestations of syphilis.

Uterine Cancer and Adjacent Tissues.—By J. A. Sampson. See MEDICAL RECORD, Vol. 78, page 36.

Repair of Cementum.—M. H. Fletcher states that it is a fact of much importance to know that cementum will reform when it has been removed from a root or cut into grooves. Nodules of cementum form on a broken surface of ivory of a human tooth, much as it is on the roots. It seems that alveolitis is treated too much without any definite idea of what processes are called into play in healing. The proper course is to encourage free activity and reproductive power of the cementum to form a new bond of union. One should aid Nature by making frequent fresh wounds in the socket without destroying any process of repair already begun. If systemic conditions are unfavorable for healing processes they should be looked after, but if Nature is encouraged she will accomplish what may seem to be wonders.

Improved Sphygmomanometer.—E. H. Goodman describes a suggested improvement in blood-pressure apparatus to avoid continuous pressure on the rubber bulb while taking the reading.

Apparatus for Proctoclysis.—M. D. Bird describes a new appliance for heating salt solution for proctoclysis It consists of a galvanized iron box covered with asbestos and sole leather, 9 inches long, 6 inches wide, 6 inches at greatest height, being dome-shaped, one end closed, the other open, with an opening ¾ inch in diameter at top of closed end, and a loop ¾ inch in diameter at top of open end, allowing a ½-inch tube to be passed without trouble; an electric lamp socket is fixed on the inside of the closed end and fitted with a 4-candlepower lamp, 12 feet of silk-covered copper wire with plug for attachment to electric light fixture, attached to lamp through the closed end. The advantages of the appliance are the following: It is simple, efficient, and durable. It will not get out of order, keeps a constant temperature, and will not burn the patient, or soil or moisten the linen. If a 16-candlepower lamp is used the bed will be warmed also when the apparatus is used for shock. The patient cannot be injured in changing position or by lying on the appliance. It reduces the labor and attention required of the nurse. The appliance slides on the terminal portion of tube, there being no fixed segment; therefore the reservoir can be placed any distance from patient without removing end portion of tube, which should be 16 inches in the bowel.

New Reflex Signs in Meningitis.—W. P. Northrup states that Brudzinski's new sign in meningitis is probably one of the best signs in the diagnosis of this disease. It comprises two reflex phenomena, the identical reflex and the contralateral reflex. The identical reflex is elicited by forcibly flexing the head on the chest, when the arms and legs regularly assume a flexed position. The contralateral reflex is produced by passive flexion of one leg, which causes the fellow to be drawn up in the same way.

Preparation of Bacterial Suspensions.—C. T. Burnett describes a simple apparatus for this purpose.

Treatment of Puerperal Eclampsia.—F. J. Plondke describes his method of treating puerperal eclampsia by means of combined venesection and infusion. Nearly all pathologists agree that the convulsions and concurrent symptoms are the results of irritation of liver and kidney cells, and of the cerebral centers by toxins circulating in and distributed by the blood-current. He follows with modern precautions as to antisepsis and prevention of air in the vein, the usual technique of phlebotomy, using a double ligature, one above and one below the incision into the superficial vein. After withdrawing a certain amount of blood from the distal portion and performing at the same time infusion into the proximal end of normal salt solution at the proper temperature, in both cases through thin-walled glass cannulas, the ligatures are drawn tight and the vein closed. The amount of blood withdrawn ranged from 15 to 32 ounces; the quantity of normal salt solution introduced varied from 1 to 2 quarts and averaged about 40 ounces. The author claims nothing new in the operation except the combination of the two methods, infusion and withdrawal of blood, taking away some of the circulating toxin and diluting the remainder. Three cases are reported in which the method was used with success.

The Situation as Regards Salvarsan.—W. A. Pusey concludes that indications at present are very strong that we are on the verge of a period of indiscriminate and reckless use of salvarsan that will result in disappointment in that valuable remedy and—what is more important—in damage to many syphilitic patients, chiefly from neglect of established measures of treatment. In the light of even the brief present experience with 606, it may be said with confidence that the agent has failed as a *therapia sterilisans magna;* it does not destroy the infection; and it does not rid the syphilitic patient of his syphilis. The belief that salvarsan cures syphilis in man depends on the following considerations: 1. The destruction of the spirochetes. 2. The reversal of the Wassermann reaction. 3. The removal of the clinical manifestations of syphilis. The evidence is becoming increasingly strong that salvarsan does not permanently and completely cause any of these results. It has a striking effect on spirochetes, but the sudden disappearance of spirochetes from lesions is no evidence of an overwhelming attack on the disease. The drug may cause the disappearance of spirochetes from a chancre within twenty-four hours and greatly reduce their number or cause their disappearance from deeper lesions—but mercury may do the same thing. If one were to take any warning from the accumulated experience of generations in syphilis, it would lead him to expect that the apparent disappearance of the spirochetes was but a lull in the invasion and that they would return. And that is exactly what is coming to light. Disappearing spirochetes are returning, it may be, even at the site of the original lesion, where their disappearance has been regarded as of such significant importance. The most important evidence as to the value of 606 is the effect on the clinical manifestations of syphilis; and here experience indicates great variability. These variations extend from cases which are "refractory" to the drug, and show no effect, to cases in which strikingly good results are seen. As a rule there is in active early syphilis—the stage at which most would be expected from a remedy that cured—distinct and positive improvement. Sometimes the symptoms entirely disappear—as happens from mercury or even without treatment—but that, even in these cases, no cure is obtained is shown by the definite tendency to recurrence that the later literature is revealing. Of the dangers of salvarsan one is least able to speak at present. We do not fully know them. The evidence is large that immediate risk of

serious accidents from the remedy is small. But enough is known to show that dangers exist. There is good ground for the belief that a larger proportion of serious accidents are occurring than would be estimated from the literature. There is great diversity of opinion about technique of efficient administration. Injections in neutral emulsion, in alkaline solution, or mixed with oil, into the subcutaneous tissue, into the muscles, or into the veins, or combinations of these various methods of administration are succeeding each other. The hope of the complete destruction of the spirochetes of syphilis in an infected patient is practically abandoned, and two or three or more injections are being used. And, finally, the recommendation of the use of salvarsan and then mercury, as heretofore, is the last evidence that the new agent is not equal to its proposed mission. It cannot be emphasized too strongly that the situation with 606 is still experimental. The present experience shows that it does not cure syphilis and that one is not justified in holding out to patients any hope of cure by it, but that it is likely to prove a useful remedy in syphilis, with mercury, however, as before, one's chief dependence

Preliminary Education of Medical Student.—Sir Henry Morris discusses certain regulations with reference to this subject as recommended in the report of the education committee presented to the General Medical Council. He proposes that the preliminary scientific studies should be pursued by the students at their schools, leaving the five years medical curriculum free for the study of the strictly professional subjects—anatomy, physiology, and medicine in its various branches.

Ultrachronic Pulmonary Tuberculosis.—H. B. Shaw reports a series of five cases which show that tuberculosis of the lungs may reveal signs at the beginning and end of periods of fifteen to twenty-five years. Each patient had pursued an indoor occupation, except one who had probably been advised to take up the work of a 'bus conductor in order to get open air. The author concludes with an expression of the hope that others will be found who will supply evidence of as great or greater chronicity in patients suffering from pulmonary tuberculosis. The more such evidence is accumulated the better it will be for the subject of the treatment of the malady, for it will give support to those who, while giving fullest credence to the benefits to be derived from sanatorium treatment, feel that after hygienic rules have been learned the patient may in suitable cases carry out the cure of the disease in his or her ordinary surroundings and while carrying out the duty of a wage-earner.

Rare Causes of Acute Abdomen.—W. H. Battle refers to cases presenting acute abdominal symptoms which resemble rather closely some of those manifested by the more common examples of perforation of the hollow viscera. In acute hemorrhagic pancreatitis, which is most difficult to diagnose, the symptoms are referred to the upper abdomen, and, as they are very urgent and accompanied with much pain, early operation is generally permitted if suggested to the patient. Yet on opening the peritoneal cavity there may be nothing abnormal presented at first sight, whilst the blood-stained fluid usually present, being small in quantity, may be overlooked as a sign of disease. And in the early stage of this illness not only may the effusion of blood be of small quantity and possibly unnoticed, but there may be no fat necrosis, the only sign which can absolutely be relied on at the time. The other acute abdominal conditions which most clearly resemble it clinically are: (1) perforations of the stomach or duodenum; (2) perforations of the appendix; (3) acute intestinal obstruction; (4) acute cholecystitis with perforation of the gall-bladder; (5) acute irritant poisoning; and (6) very rare conditions, such as embolism of the mesenteric artery, rupture of a liver abscess or hydatid, etc. Acute dilatation of the stomach is a rare condition, the origin of which is sometimes doubtful; it may follow an operation involving the peritoneum. An attack starts with copious fluid vomiting, epigastric pain, and distension, which becomes diffused; the action of the bowels is irregular; signs of extreme collapse are present. Toward the end of a severe case complete atony of the stomach may lead to cessation of the vomiting. Of physical signs, the most valuable, when it is present, is succussion, but it is important to remember the possibility of the occurrence of such a condition in the acute abdomen. Unless relieved by evacuation of the stomach contents it usually proves rapidly fatal. The extreme distention of the abdomen and generally severe condition may lead to a diagnosis of acute peritonitis, or if there is constipation intestinal obstruction may be thought to be present. Operative treatment is sometimes absolutely necessary in hemorrhage from gastric or duodenal ulcers. It may be the only means of saving life, but the indications for its performance should be clear and definite. In some cases it may be possible to find and deal with the exact cause of the hemorrhage; in others it will only be possible to treat the distension of the stomach (by gastroenterostomy) on which the occurrence of the bleeding so frequently depends. It may be the wiser plan, when possible, to perform the operation of gastroenterostomy, although the local trouble has also been directly treated. In dealing with these cases it may be advisable to remember the possibility of the hematemesis being of hysterical origin, for such a condition is always amenable to medical treatment, and should not be submitted to operation under any circumstances. By enterospasm is now recognized a condition in which there is a spastic contraction of the muscular wall of some part of the intestines; there is no obvious structural change in the bowel, and the phenomena are usually regarded as being dependent upon some abnormal action of the nervous mechanism. The spasm may give rise to symptoms of varying intensity, from those of chronic constipation to such as simulate acute intestinal obstruction.

A Case of Interstitial Gestation.—A. H. N. Lewers reports a case of this condition and remarks how important it is in cases of interstitial pregnancy to recognize its presence as soon as possible and to operate without delay. In the case narrated the diagnosis was not absolutely made before the abdomen was opened. It was evident, however, that the patient was seriously ill and in great pain, and that there was an abnormal swelling to the left of the uterus and closely connected to it. In the presence of such conditions it is undoubtedly the best thing to perform laparotomy, and ascertain exactly what is wrong. A point of some interest in the history of cases of interstitial gestation is that usually there is persistent amenorrhea up to the time when the case comes under observation, whereas in other forms of tubal pregnancy

more or less irregular hemorrhage is found to have occurred in the great majority of the cases. A point requiring consideration during the operation in interstitial pregnancy is as to whether it is possible to excise the sac, or whether it is better to perform hysterectomy. No doubt in some cases, where the sac is small, it may be safely excised. When, however, the sac is as large as it was in the case recorded the author feels sure the safest plan is to perform hysterectomy.

The Cardiac Diastolic Sound and Impulse.—T. Fisher refers to the possibility of the sound being incorrectly thought to indicate the presence of valvular disease. The sound, however, always seems to the author to be possessed of more than ordinary interest, and when one considers its frequency it is perhaps surprising that it has not been more often a subject for careful investigation.

British Health Resorts.—N. Wood describes the advantages these possess as climatic stations as well as for their mineral waters.

Iodine as a Disinfectant.—W. Evans states that he thinks very highly of the iodine method of sterilizing the skin. It is simple and thorough; it causes less discomfort to the patient and has a less harmful effect on the skin; and when it is employed stitch abscess is decidedly less rare than when the ordinary antiseptic compress has been employed. The application of iodine is certainly liable to cause some irritation to the eyes and nose of those who apply it, though there are great individual differences in this respect. The irritation to the surgeon and his assistants is much less if the iodine is dissolved in rectified spirit than if methylated spirit be the solvent employed. Chassevant used chloroform as a solvent, 30 parts of it dissolving 1 part of iodine, and it is believed that this solvent would have some advantages. It is hardly necessary to say that it is essential that the part should not be washed before the iodine is employed, or if it is considered that washing is really necessary several hours should be allowed to elapse between the washing and the application of the iodine.

Inhalation Treatment of Pulmonary Tuberculosis.—I. Burney Yeo refers to the many clinicians who have testified in favor of the inhalation treatment that he first advocated in 1882.

Perithelioma of the Great Omentum.—W. G. Nash describes a case of this condition and alludes to its extreme rarity.

Acute Phosphorus Poisoning and Acidosis.—H. L. Tidy emphasizes the connection of the secondary stage of acute phosphorus poisoning with acidosis. There is a marked similarity between delayed chloroform poisoning and the secondary stage of phosphorus poisoning. Thus there is a period of several days before the onset, and the symptoms and post-mortem appearances are similar. For these reasons one is justified in attributing the two conditions to a similar pathological state of the tissues, and one may classify together the second stage of phosphorus poisoning, acute yellow atrophy, delayed chloroform poisoning, the toxemic vomiting of pregnancy, and other conditions undoubtedly associated with acidosis.

Digitalis Heart-Block.—E. E. Laslett states that he has had under his care a patient in whom he produced partial heart-block by the administration of digitalin, and certain observations made during this period tend to show that in this case at least the heart-block was produced through the medium of the vagus nerve and not by direct action on the muscle.

Technique of Intravenous Injection of Salvarsan.—O. Grünbaum describes the details of this technique.

Zomotherapy in Tuberculosis.—J. Héricourt states that he and Charles Richet had some years ago called attention to the remarkable effects of a diet of raw meat in enabling animals that had been inoculated with tubercle to resist infection, and in spite of the technical difficulties inherent in the administration of raw meat in any form to human beings the method has been tried and their conclusions confirmed by numerous observers; in fact, raw meat has become a recognized and important factor in the treatment of pulmonary and other forms of tuberculosis, as well as in anemia, chlorosis, and similar states of *misère physiologique*. The author cannot offer any scientific explanation of its action. At the time of the early experiments the theory of antitoxins had just been elaborated, and naturally enough the quasispecific action of muscle plasma in tuberculosis was attributed to the presence of some antitoxic substance. Bearing on this hypothesis is the fact that tuberculosis never invades muscle fiber, and the well-marked muscular atrophy that occurs in phthisical subjects suggests the possibility of the muscles having been sacrificed in the defence of the organism. On the other hand, the presence in the raw juice of enzymes, ferments, and diastases which play such an important part in nutrition and in the struggle against infections may conceivably account for the activity of muscle plasma. It may be, of course, that muscle juice acts merely as a special stimulant of the nervous system. The slight but quite characteristic exhilaration that follows the ingestion of somewhat large amounts of muscle plasma militates in favor of the theory of nervous stimulation, and the good effects of zomotherapy in affections other than tuberculosis, neurasthenia, for instance, admits of a similar explanation.

The Treatment of Venous Trombosis Mainly from the Surgical Aspect. Sir William Bennett.
Some of the Rarer Occurrences in the Rheumatism of Childhood. F. J. Poynton.
Kidney Pain. E. H. Fenwick.
The Prevention of Heart Disease. W. Calwell.
The Treatment of Rodent Ulcer. E. G. Little.
Excision of a Cancerous Segment of the Esophagus; Restoration of the Esophagus by Means of Skin Flap. W. A. Lane.

Venous Thrombosis.—Sir William Bennett states that the two main factors in the occurrence of this condition are the state of the blood on the one hand and the state of the vessels in which the blood circulates on the other. It seems at first sight that actual surgical treatment of thrombosis is narrowed down to a somewhat limited application, for the ideal case must be one in which the clotting is local and limited, and if in a case in which recurrence has happened, the thrombosis must be in the same place, or at all events in the immediate neighborhood of the original attack. Under those circumstances there is no doubt that the tendency to recurrent thrombus can generally be obviated by removing the abnormal veins which originally excited the clotting of the blood in that situation. There are two sorts of thrombi which are dangerous. One of these, which the author calls "creeping thrombus," occurs in some superficial vein and gradually travels towards the central parts. The other dangerous condition is in connection with the detachment of emboli. Both of these types are at times amenable to surgical treatment. If a thrombus is found to be traveling quickly, and seems to take less notice than usual of these valvular stops, it is without doubt the best thing for the patient that the vein should be at once interrupted on the proximal side of the clot, in order to prevent its progress upward. In the case of thrombosis in a varicose vein the proper procedure is the interruption of the vein above the upper margin of the clot, keeping well clear of it, by dividing it between two fine catgut ligatures if there is sufficient room for so placing them, the thrombosed portion of the vessel being at the same time removed if it is not too extensive. When a thrombus occurring in a superficial vein is obviously septic it should at once be removed with the portion of the vein involved. The most striking example of the effects of well-advised operation in thrombosis is sometimes seen

in cases, usually septic, in which a thrombus is giving off emboli to the grave peril of the patient. Operative treatment of thrombosis with embolism must, excepting cases in which the internal jugular is concerned, be limited for the most part to superficial veins. Thrombosis occurring in a normal vein is always more or less serious. On the other hand, in veins which are sacculated or pouched a clot may form which is of little importance apart from the discomfort which it causes and the occasional liability to localized suppuration. The most interesting point in this respect is the frequent occurrence of harmless clots in the veins of old people, especially in the legs. As to the best means of promoting rapid resolution of clot, although various methods have been advanced with confidence, the author finds the older plan of compresses of lotio plumbi cum opio locally, with the internal administration of iodide of potassium or sodium with alkalies and a minute dose of opium, accompanied by the free consumption of fresh lemon juice, the most satisfactory measures. The best support for these limbs after thrombosis is a well ventilated bandage of the crêpe Velpeau kind, which can be applied without "turns" like a puttee, and can at any time be adjusted to meet the varying tension of the part. A rubber bandage is inadmissible. Speaking generally, the only conditions in varicose veins which can be operated upon with advantage are three—localized thrombus in some pouch or dilatation; trophic changes occurring in the skin about a sacculated or tortuous vessel; and localized pain such as sometimes occurs when a nervous filament becomes stretched or irritated by inflammation or rapid increase in size of a vessel with which it is in relation. In either of these conditions the removal of the portion of the vessels involved is a rational proceeding, which may indeed sometimes be urgently called for. The indications for massage must be carefully studied. If, the patient having been previously in the upright position, when the part is placed in the horizontal posture the dilated veins empty themselves immediately—behaving, in fact, as they would do in an ordinary case of varicose veins—massage may be used with impunity.

Rarer Occurrences in Rheumatism of Childhood.—F. J. Poynton discusses the following conditions that have been observed in the course of rheumatism in childhood; rashes, erythema nodosum, venous thrombosis, tachycardia, mastitis, and epistaxis. The usual forms of rash are urticarias and erythemata. Sometimes the latter are difficult to distinguish from scarlet fever. Psoriasis is occasionally associated with rheumatism. Some cases of purpura are of rheumatic origin. Herpes may occur irrespective of the use of arsenic. The author reports 14 cases which show that there is some close connection between erythema nodosum and rheumatism, but the impression that he has is that the condition is possibly not a manifestation of rheumatism in childhood. He is certain that heart disease is unusual in an ordinary attack of erythema nodosum, while it is very frequent in true rheumatism. Thrombosis of the large veins during rheumatism is a complication that is met with in severe examples of acute rheumatic endocarditis, and at the present time it is not decided whether the lesion is rheumatic in origin or is a mechanical result of the gross heart disease. In all the cases the author has met with the vessels affected have been the large veins in the neck and upper extremities. Tachycardia is an occurrence of considerable interest. In the presence of rheumatic heart disease in adults, one recognizes clearly that tachycardia is not an infrequent and is sometimes an extremely dangerous symptom in mitral stenosis. It appears to occur more frequently in mitral stenosis than in other valvular lesions, and may be paroxysmal in onset and character or more or less persistent. Further, it would seem that some cases are much more prone to tachycardia than others. With these points in mind the author has always watched for this symptom in children, and has assured himself that in some instances tachycardia may appear in the first illness, and may be followed later by mitral stenosis, and that when the stenosis appears one may then have a condition resembling the mitral stenosis and tachycardia of the adult. In such a case as this it is clear that the rapid action of the heart, although doubtless encouraged by the mitral lesion, is not in reality dependent upon it; and this in turn raises the question as to the explanation of tachycardia in mitral stenosis. There is a very important group of rheumatic cases in which the myocardium suffers out of proportion to the valves, and in these cases one will generally find tachycardia and irregularity are prominent. Such cases closely resemble the conditions that sometimes arise after influenza or diphtheria. A symptom that the author has met with in girls who have suffered from rheumatism has been tenderness and slight inflammation of the breasts. Epistaxis may occur at the commencement of an attack, during the illness, or as incident in the more quiescent phases of a long rheumatic history. Exceptionally it may be very severe, but as a rule it is moderate in degree and not of any moment in itself. It is not by any means necessarily associated with obvious nasal disease, although the author believes that sufficient emphasis has not been placed upon diseased conditions of the nose in rheumatic children as a possible source of infection.

Kidney Pain.—E. H. Fenwick states that the commonest structural change accompanying kidney pain is a distended pelvis; the commonest cause of kidney pain is dilatation of the renal pelvis. A consuming thirst is a danger signal in urology, because it is the first decided and noticeable symptom of uremia, in that it appears before any alteration in the urine. The author calls attention to the clue which a sleep posture may afford one in locating disease in the kidney. He lays down the axiom: If the patient is forced to sleep on the aching side, the kidney is still movable, and the pelvis is locally irritated. If the patient *must* rest on the unoffending side, the aching kidney is fixed and its surface is inflamed (corticitis). As a corollary, one of the first symptoms of return to health after removal of a stone from the kidney is that the patient can sleep easily on the unoffending side, and the marked sign of convalescence after a sharp attack of coli-bacillary nephritis of one kidney, in which, of course, the cortex has been involved, is that the power returns of sleeping on that kidney. Intermittent diuresis marks some dilatation of the renal pelvis. This diuresis points to some interference by tug or torsion with the vasomotor influence of the renal vessels. The author has found that fully 80 per cent. of cases of marked renal pain, not caused by stone, tubercle, or cancer, were characterized by the presence of a dilated pelvis. To him it was the hall-mark of renal pain, and he used to gauge the size of the pelvis by the number of finger-tips he could introduce easily into the renal sinus by rolling in that structure. Many of the simpler forms of bent or kinked ureter are the net result of three causes: Some increases in the vertical mobility of the organ, some softening of a dilated pelvis, and some axial rotation of the kidney. The character of the pains induced by distention of the renal pelvis is varied. First, there is the pang associated with the sensitive orifice of the pelvis. The pain which marks its mechanical abrasion, closure, or distention is felt in the hollow of the loin, just where an angle is formed between the last rib and the erector spinal. Second, there is the pain due to the movable organ, which is relieved by a kidney belt. With an infected pelvis a new form of pain is added, and when the inflamed pelvis is occluded the pain is agonizing. In addition to the local pain, the radiations go down

to the groin and leg, and the relief from rest, time, and morphine is less, for it depends on the subsidence of the actual attack of pelvitis.

Prevention of Heart Disease.—W. Calwell in attempting an estimate of the chance either of prevention or of abortion of the various kinds of heart disease, adopts a clinico-bacteriological or pathological basis for his classification. First there is the infective endocarditis group, not rheumatic. This is at present a small group, but as bacteriological knowledge becomes more exact and complete it will grow. Second, the rheumatic fever group is the largest division. It was hoped that the salicylate treatment would lessen cardiac complication; but no proof of this exists. It is common experience to find that a case benefits considerably at first by the salicylate, and then hangs fire, with mild exacerbations even under heavy dosage occurring alternately with periods of improvement. This condition reminds one closely of the recorded effect of the arsenic preparations on the trypanosomes, where the parasite develops an immunity to the remedy. The salicylates seem to lose their power, or the problematical microbe perhaps develops an immunity. Accordingly the author suggests the experiment of large and heavy dosage in the very early days of the disease. The third group is that form of heart trouble due not infrequently to exertion undertaken while out of training, or after a full meal, or while recovering from one of the minor infections, such as influenza, in which the heart muscle is still suffering from the toxin, or in chlorosis. Sometimes permanent dilatation and incompetency are left, even leading, years afterward, to sudden death. Fourth, there is the great group of degenerations, including angina pectoris, fatty degeneration, arteriosclerosis, atheroma, and valvular thickenings and degenerations. Among the causes of early degeneration are alcoholism, in which the toxic effect arises from the excessive consumption of beer (Munich heart, drayman's heart), or from the alcohol alone, as in whiskey drinkers. It is not so much the question of pure alcoholism as of alcoholism combined with physical strain, such as is seen typified in soldier and shipwright. The next cause is syphilis, whose injurious effects are chiefly felt in the vessels, not in the heart. Prevention of heart disease thus embraces (1) more accurate registration of deaths, so that the huge group labeled "syncope" may be analyzed; (2) the labors of the clinical bacteriologist to teach one what is rheumatic fever and how one may prevent it; and (3) lastly, a spread of real knowledge and education, so that men may learn not to treat their heart and blood-vessels as a careless and reckless schoolboy treats his bicycle, but as a skilled engineer treats a strong yet delicately balanced piece of complicated mechanism that reacts quickly, silently, mysteriously, to every touch of the skilled hand.

Treatment of Rodent Ulcer.—E. G. Little states that in the treatment of rodent ulcer the decision in practical experience goes against the operating surgeon in the majority of instances. The choice at present lies between x-rays, radium, actual cautery, ionization, and freezing. The author favors the method of freezing by means of carbon dioxide now.

Excision of Cancer of Esophagus.—W. A. Lane describes a case illustrating a method of treatment as follows: The principle of the operation is to excise the portion of the esophagus affected by cancer together with any glands, keeping well away from the diseased area, and to replace the segment of esophagus removed by means of a strip of skin cut transversely from the neck, and retaining an attachment and blood supply, the continuity of the esophagus being completely restored. After an interval of sufficient length for the firm union of the skin esophagus to the portion of the normal esophagus at the lines of section, the attachment of the flap of skin by its base to the skin of the neck is divided, and any lateral aperture in the skin esophagus which may remain is closed. Except when the growth involves the extreme upper limit of the esophagus or invades the upper aperture of the larynx it would probably be possible to avoid performing tracheotomy. Till the edges of the skin esophagus have united to those of the esophagus a tube for feeding purposes should be retained in position.

Typical and Atypical Pulmonary Phthisis.—According to von Hansemann modern diagnostic methods, such as serodiagnosis, Röntgen photography, etc., have led to the differentiation of atypical forms of pulmonary consumption. In many instances Koch's bacillus is never found, or when present represents only a secondary infection. We have chronic tuberculosis, or what purports to be one, which may really be a bronchiactasis, lung syphilis, or pneumonokoniosis. Even certain cases of cancer may impose themselves throughout as tuberculosis. Varieties of true tuberculosis may, as is well known, differ very much among themselves. Thus a condition which is really a miliary tuberculosis may simply remain stationary and may never show the diazo reaction. In a word, phthisis and mixed infection never develop. On the other hand, chronic bronchopneumonia may become tuberculosis. The best method of distinguishing between genuine and atypical tuberculosis is the localization. Typical forms begin invariably in the apices or at least the upper lobes. Not only tuberculosis, but most of the chronic diseases which attack the lungs, and which are in consequence sometimes found in conjunction with tuberculosis, show a similar tendency to attack the upper lobes. No matter how the tubercle bacillus reaches the blood, lungs, etc., it seems to find its way to the apex. There is evidently an anatomical defect at fault here, for we seldom find the so-called phthisical chest without the presence of apical tuberculosis. Atypical phthisis may attack any part of the lung at will, the apex not necessarily excluded. In all these cases there is a tendency for the bacillus to be infectious secondarily—in other words, to be grafted on an entire series of chronic diseases. In diabetes there is no antecedent disease of the lung, but the tissues are especially vulnerable and may be attacked by a variety of germs, including the tubercle bacillus, which may be found in any portion of the lung. Generally speaking the prognosis is graver in the atypical forms, because the typical disease often heals spontaneously in its earlier stages and is also amenable to climatic cures.

Syphilis Maligna and Salvarsan.—Buschke claims that syphilis maligna is a vague term. Some authorities make it equivalent to galloping syphilis, but a distinction is possible between the two. The author states that syphilis maligna shows itself in the secondary stage, the cutaneous lesions not being gummata but deeply ulcerating papulopustular syphilis. At the same time the inner structures show involvement—the entire body seems under the influence of the virus. The chancre lymphadenitis, and early eruptions in these cases show no peculiarities. The special state—syphilis maligna—manifests itself in a relapse of secondary lesions. There are severe fever and a general reaction, which herald the sudden appearance of the malignant state. Moreover, this type of cases seems to be without known exciting cause, such as alcoholism. It agrees remarkably well with the syphilis of the first outbreak in Europe. There is no evidence that these cases were derived from similar cases. It appears that individuals with this condition have but limited protection from antibodies. They are also not very amenable to treatment except with 606. The author believes that they are due to a symbiosis of the spirochete with an unknown

germ. In lesions of typical syphilis maligna he could find no spirochetes. Apes inoculated from lesions of syphilis maligna developed ordinary syphilis, but nevertheless without spirochetes. The disease was propagated through other generations of apes, but spirochetes never appeared. One ape developed a tuberculoserpiginous ulcer which refused to heal. After numerous inoculations of syphilis maligna, which proved chiefly negative as far as that condition was concerned, cases enough were accumulated to show that the ape could, in a minority of inoculations, develop a condition resembling syphilis maligna in the main. The spirochete at no time appeared. The inoculated material all came from men with syphilis maligna. The author is at much pains to isolate his syphilis maligna. Even the scars of the cutaneous lesions are said to be characteristic. Syphilis maligna may occur for a time with ordinary syphilis, spirochetes being present in the latter and absent in the former. Syphilis maligna reacts well to "606" despite absence of spirochetes.

Salvarsan Therapy.—Ehrlich, in a long contribution, makes use of the word salvarsan as the familiar and commercial name of "606," and takes occasion to reply to all of his critics since the introduction of the remedy. He does not appear to abate a jot of his original doctrines, and has adhered to his principles to hold the remedy back until a certain number of thousands of reports had been received from the exhibition of the drug as furnished by himself, his own indications and dosage being adhered to. The exaggerated optimism of others did not originate from his own teachings, which were conservative. A certain pessimism has been the natural results of the unjustified optimism, as was to be expected Ehrlich replies naturally to men of eminence only. Several columns are devoted to the claim of Finger that salvarsan is neurotoxic. Finger, he states, must have been unaware of his own remarks as to eye cases and to contraindications in the use of salvarsan. At the same time many favorable reports have come in as to the use of salvarsan in severe syphilitic affections of the retina and optic nerve. Space does not suffice to follow Ehrlich's article to its conclusion, but he seems amply able to defend himself against all critics. If a disastrous result of the use of "606" is emphasized by some distinguished authority, Ehrlich is usually able to show that the drug was given against his own orders, and that he had even warned against its use in such connection. If some one seeks to show that salvarsan has produced injury of certain structures, especially the cranial nerves, Ehrlich has a host of cases to cite in which salvarsan acted marvelously in actual syphilis of such organs. It is evident that Ehrlich has some years' start of his critics and that he is therefore able to outargue them for the present.

Postmortem Auscultation Sounds.—Hering gives a brief account of a phenomenon hitherto unobserved. In a woman patient whom he saw die, and tested for the usual signs of death, a murmur was heard during auscultation of the pulseless heart, at the lower border of the sternum. Two assistants also heard the sound. The murmur ceased after some two minutes, and did not return. It was not rhythmic, but continuous. One of the writer's assistants has since heard the same postmortem murmur in another case. It lasted half a minute. The author speculates much as to the nature of this phenomenon, but can only conclude that it is due to the last flicker of the dying heart.

Significance of the Corpus Luteum for the Sexual Cycle.—Leo Loeb sums up his studies of this subject to date as follows: The corpus luteum, besides being instrumental in placentation, also influences the periodicity of the sexual cycle of the female of mammals. Both in the pregnant and non-pregnant, the corpus luteum prolongs the length of the period between two ovulations. Conversely removal of the corpus accelerates ovulation. In the pregnant state, not pregnancy, but the delayed function of the corpus luteum delays a fresh ovulation.

Subcutaneous Feeding with Grape Sugar.—Kausch discusses this form of alimentation along with intravenous infusion and pronounces it harmless at least and indicated in persistent vomiting, cholera and the like. The subject is not a new one, but has hitherto been discussed chiefly as an adjunct in bringing up the calories of a certain diet, the utilization being small—so small in fact as to be negligible. The author advocates for subcutaneous injection 1,000 c. cm. of solution beginning at 2 per cent. and extending to a superior limit of 5 per cent. per diem. By the intravenous method 1 000 c.cm. of a 5 per cent—7 per cent. solution are decidedly well borne. The sugar is not excreted for a while, but after several days begins to appear in the urine. More than 7 per cent. solution shows glycosuria soon after infusion. But generally speaking, even in higher percentages, the loss of sugar is very small in proportion to the amount infused. Grape sugar solution consists of the desired percentage of the latter in saline solution which has been filtered and boiled. When infused into a vein from 4 to 8 drops of an adrenalin solution (1:1,000) are added. Patients prefer the intravenous method. It is true that the more miserable the state of the patient's nutrition the better the infusion of sugar is borne and utilized. We have to speculate on how much of this benefit is due to the saline infusion and adrenalin. Clinically the benefit seems more sustained. The sugar disappears and must therefore be oxidized. Albumin is spared, and up to 500 extra calories of nutriment are afforded by the infused sugar. The author cites certain cases of inanition in which recovery or improvement occurred. It is not a surgical remedy, *per se*, but rather indicated in some of the severest medical diseases (cholera).

Herpes Zoster After Injections of Salvarsan.—Bettmann reports cases of herpes zoster following an injection of "606" which might be regarded either as herpes zoster arsenicalis or the ordinary infectious form, the latter view being improbable. Zoster arsenicalis is very common in the course of an arsenical treatment of various diseases. Not only herpes zoster, but various forms of herpes simplex have also been recorded after the "606" injection. The author has seen a dozen cases comprising herpes cabialis, h. progenitalis and angina herpetica.

Symptomatology and Frequency of Intrathoracic Goiter.—Kreurfuchs sums up a personal article as follows: Intrathoracic goiter is by no means rare, but is diagnosticated with difficulty unless the *x*-ray is used. The most important symptoms of intrathoracic goiter are dyspnea, palpitation, difficulties of swallowing, cough, hoarseness, stridor, blue lips, dilatation of veins of the neck and of the anterior, superior portion of chest, dullness over manubrium sterni and low seat of the larynx. One must exclude the presence of extrathoracic goiter. Nevertheless, there are intrathoracic goiters which give no symptoms save those furnished by the *x*-ray.

Sepsis from the B. Friedländer.—Rolly, in an article on the subject, says that certain cases on record of Friedländer sepsis were of the cryptogenetic character. Others seem to have originated from the biliary passages, urogenital system, ear, etc. The bacillus has been cultivated from the blood in twelve cases. There is nothing typical about this disease from any point of view and the diagnosis can be made only by bacteriological methods.

Book Reviews.

A Text-Book of Bacteriology. A Practical Treatise for Students and Practitioners of Medicine. By Philip Hanson Hiss, Jr., M. D., Professor of Bacteriology, College of Physicians and Surgeons, Columbia University, New York City, and Hans Zinsser, M. D., Associate Professor in Charge of Bacteriology, Leland Stanford, Jr., University, Palo Alto, Cal.; with One Hundred and Fifty-six Illustrations, Some of Which Are Colored. New York and London: D. Appleton & Co., 1910.

No science or branch of the sciences has now a wider scope or has made and is making more rapid advances than that of bacteriology. Indeed, the progress being made is so rapid that it is difficult for bacteriologists themselves to keep in intimate touch with all that is new in their own particular field of work. For the medical practitioner this is almost impossible. It is necessary then that there should be clearly written text-books on bacteriology which contain all that is essential to a fairly thorough conception of the science in its most modern aspects. Such a work has been provided in a most satisfactory manner by Drs. Hiss and Zinsser. The first section of this book deals with the general biology of bacteria and the technique of bacteriological study. The second section is perhaps the most important of the book; it is certainly the most interesting to the non-bacteriologist. This part discusses infection and immunity and explains the whole matter in a very lucid manner. The defensive factors of the animal organism are explained in detail and the description of the antibodies and the substances giving rise to them is especially worthy of attention.

In chapter XIX the question of anaphylaxis or hypersusceptibility is entered into at length and it is stated that anaphylaxis may be passively transmitted by inheritance from the mother without any reference whatever to the condition of the father, and without being transmitted by milk. The chapter on the facts and problems of immunity in their bearing upon the treatment of infectious diseases concludes with the statement that "the point which should be made clear is that the outcome of our attempts to treat infectious diseases is, if we have the real means in our hands, probably more dependent on the degree of adaptation of the germs than the actual powers of resistance of the patient." Our present knowledge of pathogenic organism is excellently expressed in section III, and the chapter treating of diseases caused by spirochetes is in existing circumstances peculiarly apt. Of the diseases of unknown etiology rabies is very fully discussed, while everything that is known concerning acute anterior poliomyelitis is concisely set down. The last section is concerned with bacteria in air, soil, water, and milk, and is a fitting ending to a book which contains the gist of what is known of medical bacteriology. The pictures are clear and plainly illustrative of the text, and the book throughout adequately fulfills the professed aims of its authors.

Modern Treatment: The Management of Disease with Medicinal and Nonmedicinal Remedies. In Contributions by American and Foreign Authorities. Edited by Hobart Amory Hare and H. R. M. Landis, M.D. Vol. I. Illustrated. $6.00. Philadelphia and New York: Lea & Febiger.

The title of this book indicates a correct estimate of the meaning of treatment. The author is the first to adopt the reviewer's oft repeated view that the term "treatment of disease" is a solecism, since with rare exception the modern physician treats the patient, not the disease. The management of disease is set forth in these pages by men who have made a special study of the branches assigned to them. The introduction by Dr. Hare is worthy of that veteran teacher of therapeutics, who lays proper stress upon the vis medicatrix and the importance of not hampering it. The scope of the work is evident from the following contents: Modern Pharmacology, by Horatio Wood, Jr., in which this apostle of drugs discusses a theme in which he is *facile princeps*. Prescription Writing is given in epitome by Dr. Amos Huneberger, and the question of the Untoward Effects of Drugs is creditably summed up by Dr. R. D. Rudolf, an Englishman. The title "Modern Treatment" is justified by the fact that while drug treatment is disposed of in ninety-two pages the nonmedicinal treatment occupies 442 pages. It is refreshing to compare this book with a recent edition of a "Textbook on Therapeutics," in which 706 pages are devoted to medicinal and five pages to nonmedicinal remedies. Far be it from this reviewer to deprecate the use of drugs; a half century in medicine has convinced him of their value and imbued him with the idea that they are indispensable. It is nevertheless a deplorable fact that this is the era of polypharmacy and that physicians often prescribe remedies of which they know nothing more than that some impecunious *privat docent* has praised their virtues. Climatotherapeutics is briefly discussed by Dr. W. J. Barlow, one of the most capable teachers on the Pacific Coast. This chapter should be read and pondered over by every physician who contemplates exiling his patient for health. General Exercise is intelligently presented by Dr. Thomas A. Storey, who avoids the confusion one experiences on reading the conventional treatise on this subject. Mineral Springs receive an epitomised recital by Dr. Hinsdale, a rising authority on hydrotherapy. Hydrotherapy is reviewed by Drs. Baruch and Shrady, who teach this branch in Columbia University as an obligatory part of the curriculum. They are therefore competent to present the uses of water from the clinical standpoint as a reliable guide to the general practitioner, whose ideas on the uses of water in disease are proverbially indefinite. The article on Electrotherapeutics is complete and practical, being written by a teacher in neurology; as is also the separate and illuminating chapter written by Dr. Peahler, a director of an *x*-ray laboratory. That the essay on the Rest Cure is instructive and practical is guaranteed by the fact that Dr. F. X. Dercum is the author. The same comment is justified by the article on Nutrition and Foods, being written by Dr. Julius Friedenwald of Baltimore. Serum Therapy, by that practical authority, Dr. W. H. Park, is presented clearly. The subjects of Opsonins and Vaccine Therapy are judicially treated by Dr. N. Bowditch Potter, and Glandular Therapy by Dr. S. P. Beebe. The claims of tuberculin are sifted and presented with fairness by that well-known authority on tuberculosis, Dr. F. M. Pottenger of Los Angeles.

The third chapter is devoted to infectious diseases. Typhoid Fever, the Exenthemata, Cerebrospinal Meningitis, Pneumonia, Tuberculosis, Diphtheria, Acute Articular Rheumatism, Cholera, Plague, Influenza, and Yellow Fever are discussed by men who display insight into the needs of the practitioner who would look to this work for counsel. Space admits of reference to the most striking only. In the article on Typhoid Fever Dr. D. Riesman makes the rather startling statement: "I personally hold that the management of typhoid fever has made large enough strides in other lines to warrant us in dispensing with the troublesome tub bath." While this is "a consummation devoutly to be wished," past experience of men who saw much of typhoid fever without the "troublesome tubbing" would lead one to fear that the era of dry tongues, delirium, bedsores, pulmonary hypostasis, and large mortality would be reestablished by the abandonment of the tub. Even the prevailing mild bath evidences retrogression if the reviewer may judge from a recent visit to two hospitals in which baths of 85° F. have been substituted for colder baths. For the first time in twenty years did he see early treated cases presenting comavigil, involuntaries, and sordes. This author's statistics do not agree with those cited in another part of the work. He modestly makes the concession, however, to say "the bath is still in use by many authorities, and one hesitates to discourage a practice that has such ardent advocates." The chapter on Pneumonia, by Dr. F. S. Meara, offers a résumé of the cold-air treatment. Though an enthusiast on the subject the author is too skilful a clinical teacher to omit other measures. The essay on Acute Articular Rheumatism, by Dr. Clayton, is of special value to the man at the bedside. His directions for administrating salicylic acid mark him as a man who knows whereof he speaks, which is more than can be said of all teachers.

The illustrations of this work are clear and instructive, the paper excellent, but the binding is not up to the standard. A book of reference demands special attention to binding. Altogether, the book may be commended as a safe guide to the practitioner in need of counsel.

Dust and Its Dangers. By T. Mitchell Prudden, M.D. Second Edition. Illustrated. 75 cts. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1910.

Dr. Prudden is undoubtedly a firm believer in the truth of good old John Wesley's dictum, that cleanliness is next to godliness. The healthfulness of cleanliness is fully appreciated nowadays, and the menace of a dust-laden atmosphere is thoroughly recognized. The principal object of Dr. Prudden's little work is to impress on the public the dangers of inhaling air containing numerous dust particles, especially in the production and aggravation of consumption, and this task he has accomplished well.

Fisiologia General. Por los doctores A. Pi y Suñer, Ex Catedrático de la Facultad de Medicina de Sevilla, Professor de Fisiologia general en el Laboratorio Municipal de Barcelona, y L. Rodrigo Lavin, Catedrático de Fisiologia en la Facultad de Medicina de Cádiz, Inspector provincial de Sanidad. Barcelona: Gustavo Gili, 1909.

The importance of general physiology as a preliminary to the study of what is commonly termed human physiology, but is really animal physiology, is now well recognized; and a number of text books are available, perhaps the best known of which is that of Verworn. The need of a similar work in Spanish has led the writers to prepare this very excellent treatise on the subject. The book is well printed and thoroughly illustrated with simple line drawings and diagrams, and is altogether a creditable piece of book-making. From a scientific point of view the contents are equally satisfactory. The preliminary portions are devoted to the morphology of the cell in relation to its physiological qualities, including the chemical constitution of cells and the simpler physiological phenomena of irritability and motion. There is a chapter on metabolism, on the nature and activities of ferments, all of which has been brought up to our most recent knowledge on the subject. The section on energy exchange includes the production of heat and electricity by living cells and the nature of cell movement in response to stimulation. Nuclear division as a part of the phenomena of growth is presented with unusual fulness. The second part of the work deals with the special physiology of the differentiated cell congeries, beginning with the neuromuscular system, including the excitability and conductability of nerves, and the nature of the stimuli which excite them. This is followed by a section on cellular secretion and the physical and chemical qualities of the blood, and, finally, by a very excellent chapter on the respiratory functions of the blood and its coloring matters. The work can be commended as a most excellent guide to general physiology.

State Board Questions and Answers of Forty-one States and Two Canadian Provinces. A Practical Work, giving authentic questions and authoritative answers that will prove helpful in passing State Board Examinations. Reprinted from The Medical Record. Third Edition, revised and greatly enlarged. $3.00. New York: William Wood & Company, 1910.

This volume, of over 800 pages, will prove of great assistance to all (both students and practitioners) who have to face a State Board Examination. All the more important States are here represented; and it is safe to say that anyone who can answer satisfactorily the questions here given will be able to pass any State Board. A careful study of this book is the next best thing to taking a quiz under a competent master.

Pulmonary Tuberculosis and Its Complications, with Special Reference to Diagnosis and Treatment; for General Practitioners and Students. By Sherman G. Bonney, A.M., M.D., Professor of Medicine, Denver and Gross College of Medicine, Medical Department of the University of Denver; Visiting Physician to St. Luke's Hospital, Consultant to the Denver County Hospital, Director of the National Association for the Study and Prevention of Tuberculosis, Member of the American Climatological Association, ex-President of the Denver Clinical and Pathological Society, etc. Second Edition, thoroughly revised. With 243 original illustrations, including 31 in colors and 73 *x*-ray photographs. Philadelphia and London: W. B. Saunders Company, 1910.

Perhaps the best argument that Dr. Bonney's book has filled a certain need among those desirous of informing themselves about tuberculosis is that it has passed into the second edition. Many minor details of expression, lack of clearness and statement of fact can be criticised, as, for example, the author under the caption "The Influence of Hemorrhage upon Pulmonary Tuberculosis" leads us to believe that inasmuch as it has been conclusively proved that the blood pressure has been reduced in high altitudes, there will be a corresponding lessening in the tendency to hemorrhage in pulmonary tuberculosis, while farther along in the book, under the heading "Climate in the Treatment," says: "recent studies (upon variations in blood pressure . . .) cast some doubt upon the correctness of previous views." The subject of high altitudes and its relation to blood pressure is still in moot, and it can hardly be said that any phase of it has been conclusively proved. One might also suggest that the book could be somewhat differently proportioned with advantage, particularly in view of the fact that it has been prepared more for the use of the general practitioner. There are fifty-six pages and sixty-two illustrations under the heading "Röntgen Rays," which would, the reviewer believes, make very slight appeal and be of little service to those for whom the book is particularly intended. On the other hand, the subject of tuberculin treatment is covered in four pages, although the author quotes at some length in another chapter from his "personal observations upon the use of tuberculin and bacterial vaccines." How well advised it may be for those not working largely in tuberculosis to attempt the administration of tuberculin is not a question to be discussed in a review, but the fact remains that many do, and more will, make therapeutic use of this remedy, making, as best they can, the proper selection of cases and dosage. It seems, therefore, that it would be eminently proper and needful to include in any book which aims at a comprehensive digest of the subject of pulmonary tuberculosis a detailed outline of the methods of administration and preparations of tuberculin, and particularly the clinical manifestations of excessive or too frequent dosage.

A History of the London Hospital. By E. W. Morris. New York: Longmans, Green & Company. London: Edward Arnold.

In this delightful book the author gives what is really a history of the development of medicine since the middle of the eighteenth century, for in tracing the growth of the London Hospital from its foundation at that time he also sketches in vivid outlines the progress made in the treatment of disease during this, the most fruitful, period in the annals of our art. A detailed review of the changes that have gone on in one of the world's greatest hospitals necessarily involves discussion of the important advances that have been made in medicine and surgery, and it is both interesting and instructive to consider these from this somewhat unusual standpoint. The author has been exceedingly wise in that, departing from a habit easily fallen into and customary in similar efforts, he has given what is truly a history of the hospital itself, and not a series of biographical sketches of persons, lay or medical, who have been associated with it. This may in part be due to the fact that the book is evidently intended for the general public as well as for the profession, and Mr. Morris deserves full praise for his success in making a narrative that should be equally interesting to both sets of readers. The volume opens with a description of the hospital, with all its departments, and of the general routine methods adopted in the admitting and handling of the outdoor and indoor patients. Then follow a number of chapters in which the actual foundation of the institution and its growth from decade to decade are narrated, and such subjects as the relation between the managers and the staff are discussed. In other interesting chapters the establishment of the hospital's medical school and of the nurses' training school is chronicled, and the innovations of the last twenty years are reviewed at length. The volume closes with two very thoughtful and useful chapters on hospital administration and on the future of public institutions of this sort. These alone would be sufficient to make the book of the greatest possible interest to all those having to do with hospital work, and especially to medical teachers, for the highly important topic of the function of hospitals as centers of instruction is threshed out at length. The author's nolished style gives true literary value to this "history," which is as fascinating to read as fiction, while from the mechanical side, also, the book is much more attractive than are most of the volumes that find their way to the medical man's library table.

Taschenbuch der Therapie. Mit besonderer Berücksichtigung der Therapie an den Berliner, Wiener u. a. deutschen Kliniken. Herausgegeben von Dr. M. T. Schnirer, Redakteur der *Klinisch-therapeutischen Wochenschrift*. Siebente vermehrte u. verbesserte Ausgabe. Würzburg: Curt Kabitzsch (A. Stuber's Verlag), 1911.

This pocket manual of therapeutics is a good example of *multum in parvo*. Among the many subjects that the author has crowded into its pages, in addition to a therapeutic vademecum and a comprehensive formulary compiled chiefly from continental sources, may be mentioned cosmetics, medicinal foods, the diagnosis and treatment of acute poisoning, first aid in sudden illness, maximal doses for adults and children, tables of height and weight, caloric values of foods, diet cures, health resorts, tuberculin diagnosis and therapy, and new therapeutic measures.

Die Hautleiden kleiner Kinder. Von Dr. S. Jessner, Königsberg i. Pr. Dritte Auflage. Würzburg: Curt Kabitzsch (A. Stubers Verlag), 1910.

In this pamphlet of forty-nine pages the author describes the treatment of the common forms of cutaneous disease in young children. Those who are interested in pediatric practice will find in these pages many valuable suggestions.

Society Reports.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-third Annual Session, Held at Nashville, Tenn., December 13, 14, and 15, 1910.

THE PRESIDENT, DR. W. O. ROBERTS OF LOUISVILLE, IN THE CHAIR.

The Importance of Preserving the Gall Bladder.—Dr. J. W. LONG, of Greensboro, N. C., stated that a critical analysis of eighty-six of his own operative cases had convinced him of the value of retaining the gall-bladder. Cholecystectomy should be done in the presence of new growths, especially primary carcinoma; also in gangrene when the whole thickness of the bladder wall was involved, but not otherwise, since he had had several recoveries following drainage for gangrenous mucosa of the bladder. Infection and empyema were only relative indications for doing cholecystectomy, most cases doing well under cholecystotomy. The cystic duct obstruction always present in empyema was gradually overcome under the beneficial influence of drainage and after a varying interval of one to seven days, in one instance fifteen days, bile began to discharge through the duct. Stone impacted in the cystic duct was only a rare indication for cholecystectomy, the writer never having failed to remove the stone. Even perforation could not be considered an absolute indication for cholecystectomy, the writer reporting two cases which did perfectly well under drainage. Drainage was second in importance only to removal of stones. Removal of stones could not cure a pancreatitis, but drainage did. No organ in the body once badly damaged responded so effectually to drainage as did the gall-bladder. Drainage was the *sine qua non* for curing the patient of the widespread sequelæ of gall-bladder infection. It was prudent in doing a cholecystectomy to leave a forceps rather than a ligature on the cystic duct in order to provide for a free flow of bile should untoward symptoms arise. Embryologically, the bud for the gall-bladder and that for the larger portion of the pancreas developed together; as they grew and receded from each other, their ducts remained joined. The relation of the two organs was very close anatomically and physiologically. The gall-bladder was not a storage pouch for bile, but rather was an expansion tank for the bile duct system. Its removal was always followed by dilatation of the ducts, even the lumen of the cystic duct compensating for the loss of the expansion tank. Pure bile injected into Wirsung's duct caused pancreatitis, bile mixed with the bladder mucus did not, a cogent reason for preserving this function. The only avenue through which to treat chronic pancreatitis present or in the future was the bile duct system, preferably through the gall-bladder.

Dr. THOMAS S. CULLEN of Baltimore stated they had for several years made it a practice to drain all gall-bladders, except in those cases in which there was a suspicion of malignant disease, or where there was empyema of such a character that it was impossible to drain satisfactorily, where the danger of removing the gall-bladder was not as great as that of infection from drainage.

Dr. HOWARD A. KELLY of Baltimore stated under no circumstances would he remove a gall-bladder that was apparently sound or even moderately diseased, which evidently might easily recover with drainage. Again, he would not remove a gall-bladder where there was any suspicion of trouble in the common duct or any pancreatic disease. It was best to remove a gangrenous gall-bladder or one that was suspected to be malignant.

Dr. J. GARLAND SHERRILL of Louisville said there had been a tendency to do too radical operations in this region. He had saved a number of gall-bladders that were full of pus by drainage. The reparative power of the tissues was very great and the opening became patent in a short time, and drainage of bile free.

Dr. RANDOLPH WINSLOW of Baltimore stated he had operated on a case some time ago where the duct was evidently obstructed; although bile reappeared, it did not flow. However, in the course of time nothing but mucus came from the external opening; the gall-bladder was distended and bile did not pass. There occurred stricture of the cystic duct which necessitated a second operation for the removal of the gall-bladder.

Dr. R. E. FORT of Nashville said in those cases where they had a small, contracted, rigid, friable gall-bladder, not larger than the finger, in which drainage could not be instituted, he thought it not only proper but essential to do a cholecystectomy. There were cases occasionally in which they had common duct obstruction and it became necessary to do cholecystectomy, but in other cases it was not necessary to do this radical operation.

Dr. BACON SAUNDERS of Fort Worth, Tex., stated in these old chronic gall-bladders it was necessary to continue drainage sometimes for six weeks in order to get satisfactory results.

Dr. WILLIAM B. COLEY of New York City said when he removed a gall-bladder he instituted drainage in the cystic duct and this did as much good to the pancreas as if they drained through the gall-bladder itself.

Dr. LONG, in closing, stated in gall-bladder surgery, as in all other surgery, it was largely a matter of personal equation in deciding what was the best thing to do in the individual case.

Chronic Urethritis and Chronic Ureteritis Caused by Tonsillitis.—Dr. GUY L. HUNNER of Baltimore in a paper on this subject, contended that certain cases of chronic urethritis and chronic ureteritis heretofore of obscure origin were due to tonsillitis. He recognized that the great majority of chronic urethritis cases were due to gonorrhea, most of the cases of rheumatic urethritis of the older textbooks being of this nature. Some cases could be traced to trauma and infection in childhood, or trauma and infection of nongonorrheal character in the newly married. Other cases might probably be due to onanism, and some might be classed as autoinfections, the short female urethra and the myriads of microorganisms normally present in the outer orifices being factors that would make autoinfection probable. After ruling out gonorrhea and these rarer causes of infection, there still remained a certain large percentage of chronic urethritis cases, which, in recent years, he had associated with the rheumatic diathesis. He asserted that in a large proportion of this class of cases the disease was due to infections or toxins from the tonsils, and the importance of this observation was appreciated only when we recognized that the urethritis could not be permanently cured until the tonsils were thoroughly extirpated. To substantiate his views, four cases which had had the tonsil operation were reviewed in detail, and several others not operated were cited briefly. Of the four operative cases, two had been treated for months without appreciable permanent benefit to the urethra, whereas after removal of the tonsils Case 1 recovered. The recovery was prompt, and patient had been well for fourteen months, after having had bladder trouble eight years. Case 2, after removal of the tonsils, had an irritable spot in the base of the right fauces, which for seven months gave periods of sore throat accompanied by rheumatic symptoms in the knees and urethritis symptoms. For the past four months the throat symptoms had been absent, and the joints and urethra were apparently well. Case 3 had been treated in the hospital on two occasions in the past nine years with prompt recovery from the

urethral symptoms each time. On the last hospital visit in March, 1910, the tonsils were clipped with the tonsillotome, and the patient reported a return of all her symptoms soon after going home. Case 4 had a tonsillectomy after two urethral treatments, so no conclusions could be drawn in her case as to the futility of urethral treatments, without removal of the tonsils. She had apparently recovered after having had bladder trouble three years, although only four months had elapsed since the tonsillectomy. The various possible causes of urethral stricture were discussed and two cases were reported to illustrate the possible causal relationship of tonsillitis. The fact that acute prostatic abscess sometimes followed inflammation of the tonsils suggested a possible relationship between the tonsils and certain chronic urethritis cases in males. These cases were often associated with chronic prostatitis, in which gonorrhea could be excluded as the cause, and for which no definite etiology had heretofore been obtainable.

Dr. J. M. Mason of Birmingham said it seemed that all of the cases reported had occurred in unmarried women in whom there was some possibility of nervous disturbance or reflex irritation of the urethra. He would like to ask Dr. Hunner whether he had had any cases in married women or in women whose sexual relations were normal.

Dr. G. R. Holden of Jacksonville, Fla., asked whether the discharge in these cases contained pus cells, as seen by the microscope.

Dr. Howard A. Kelly of Baltimore stated the wife of a professional colleague had been under his care for fifteen years. She had more or less malaise. Careful examination revealed pus in the urine in varying amounts, but so far as the local conditions were concerned the patient was without symptoms. She was in ill health. He catheterized and found pus came from the left kidney. He dilated the ureter on that side, washed out the kidney, she got better, and after a few months returned for further investigation and treatment. She had for twelve years been troubled with rheumatism. She had enlargement of the joints. Last spring, on examining her, he found a large, tender kidney with a good deal of pus in the urine. He drained this kidney and did a plastic on the semilunar ureteral valves. He cut down on the fascia at the end of the ureter and drained from the side. She continued to suffer with rheumatism through the summer, although she experienced some relief from the drainage in the side. This fall he took out the kidney and her rheumatism disappeared like magic.

Dr. John F. Oechsner of New Orleans said it seemed from the cases cited, without going into any other possible local infection, that the tonsils were at fault. He feared, however, that what had been said might lead to more or less universal tonsillectomy if the members of this representative body should regard the tonsils as always at fault in cases of urethritis, where the specific organism, the gonococcus more particularly, could not be determined. He would, therefore, make a plea to educate the practitioner to be more specific in determining the nature of a local infection, whatever it might be, and find out exactly where the focus of infection was.

Dr. Hunner, in closing, stated some of the cases he had had since the four he had reported were married women. These cases did not have pus in the urine. He stated they could not milk pus out of the urethra as they could in an acute gonorrheal case.

The Best Method of Exposing the Bladder for Aggressive Operations by the Suprapubic Route.—Dr. Howard A. Kelly of Baltimore pointed out the disadvantages of the method in common use, namely, of making a vertical midline incision between the recti muscles when the muscles with their underlying fascia resisted retraction, and so offered only a slit through which the bladder could with difficulty be exposed. Dr. Kelly used a transverse crescentic incision above the pubis through skin, fascia out to and even beyond the semilunar line on each side. He then separated the fascia from the muscles after the manner proposed by Pfannenstiel for operations upon abdominal and pelvic tumors. In bladder cases, however, the abdominal cavity was not opened. The recti muscles, freed from their overlying fascia, were flaccid and easily drawn apart, thus affording a very broad exposure of Retzius' space. The bladder was clearly brought into view by inflation with air pumped in through the urethra, and was widely incised in its transverse axis, thus affording a maximum exposure of the viscus. With the bladder thus conveniently opened, all parts of the organ were perfectly exposed to view and made easily accessible to operation. The whole question of dealing with extensive ulcers, papillomata, malignant disease, and cystitis requiring resection was by this means greatly simplified. Further help in bringing the base of the bladder up within reach might be secured by introducing two fingers into the vagina in women and pushing the anterior wall upward. At the conclusion of the operation the bladder was closed with fine silk or catgut sutures, the investing fascia was also carefully united with catgut or silk, and the rest of the abdominal wound closed, in suitable cases leaving a small drain extending down to or into the bladder. By this operation a maximum exposure and accessibility of the bladder, without injury to the important underlying structures, were gained, without a risk of subsequent hernia.

Dr. J. Shelton Horsley of Richmond, Va., stated for more than a year he had been using the Pfannenstiel incision as a routine measure in all suprapubic cystotomies, and he found it took very little more time than the ordinary incision, and it left the abdominal wall in a much better condition afterwards.

Dr. Ernst Jonas of St. Louis said the Pfannenstiel incision gave a very good view of the bladder. This incision had been advocated by Dr. Pfannenstiel for clean gynecological cases where there was no pus in the pelvis, and for cases in which the pelvis was badly infected.

Dr. Reuben Peterson of Ann Arbor stated the Pfannenstiel incision was only suitable for clean cases. He had had a large experience with the transverse incision for shortening the round ligaments and for operations on the bladder, and if the wound should suppurate the objection raised by Dr. Jonas held good. While the technique demonstrated by Dr. Kelly was fine for clean cases, he could see objection to this incision in suppurative cases.

Dr. George H. Noble of Atlanta stated he had made use of the transverse or Pfannenstiel incision quite frequently in cases in which he did not expect to encounter a septic process, both in placing the uterus in its normal position and in opening the bladder. A point he wanted to bring out specially was that in this dissection you could increase the opening very materially and satisfactorily by making a section of the lower ends of the recti muscles, where necessary, and get a good view. This was particularly the case where they wanted to open the pelvis to go into the peritoneum, using this incision.

Dr. Alexander Hugh Ferguson of Chicago stated he could see how this method of exposing the inside of the bladder would be of great utility to those surgeons who practised suprapubic prostatectomy, also in removing papillomata in avoiding the ureter. They must remember that there was no fascia behind the rectus muscle in this region, and that it retracted easily and acted as a bar to infection in the operative area.

Stone in the Ureter.—Dr. R. C. Bryan of Richmond, Va., reported eight cases of stone in the ureter, and then discussed the etiology, pathology, symptoms, diagnosis, differential diagnosis, and surgical treatment. As to treatment he said: The size, number, and location of the

stones having been accurately determined, the treatment resolved itself into one of two methods: (1) ureteral catheterization and lavage; (2) operation. It would seem advisable in small stones, and those located in the lower segment of the ureter, to attempt by ureteral catheterization and injection to dislodge them. This would likely occur in a fair percentage of instances. It occurred in four of his cases. If this method failed, operation was indicated. He had done only the extraperitoneal operation. It did not appear that the intraperitoneal or combined methods offered any peculiar advantage which would justify the possibility of peritoneal infection by urine leaking from a suppurating tract. An incision starting midway between the highest point of the crest of the ilium and the eleventh rib and running to the anterior superior spine of the ilium, thence parallel with and internal to Poupart's ligament for its outer three-fourths, had in his series given sufficient opening to explore the ureter from the kidney above to the bladder below. In those instances in which the stone was incarcerated in the intravesical segment the incision might be carried down to the spine of the pubes, thus giving all the room desired. The ureter was cut through its long axis, the stone removed. Catgut sutures approximated the wound, and a tube was inserted to the site. In his series there was leakage in but one case for five days, the remainder giving none at the end of two days.

The Early Diagnosis and Treatment of Renal Tuberculosis.—Dr. J. M. Mason of Birmingham reported a case in which there was extensive tuberculous disease of the left kidney, with symptoms referable only to the bladder. He said: Renal tuberculosis was, in the beginning, a unilateral infection, and might remain so for a long time. For successful treatment the patient should reach the surgeon while the disease was still confined to one kidney. The early symptoms were rarely referred to the kidney, but in a large percentage of cases were vesical and might remain so for many months. For the diagnosis, repeated examinations should be made for the detection of tubercle bacilli in the urine, and often the inoculation of guinea pigs should be resorted to. The cystoscope and ureteral catheters must be made use of to ascertain the condition of the bladder and to determine which kidney was the seat of disease, also for the purpose of ascertaining the organic and functional condition of the second kidney. The treatment consisted of prompt nephrectomy, followed by the best hygienic, climatic, and dietetic management.

Cesarean Section, with Special Reference to the Time of Operation and Its Technique.—Dr. Lewis S. McMurtry of Louisville said the operation should be performed with the same deliberate care and expedition as were observed in other abdominal operations. There seemed to be a general impression on the part of surgeons that exceptional rapidity bordering on haste should characterize the steps of the operation. There was no valid reason for this. Davis made the abdominal incision above the umbilicus, and the uterine incision just below the fundus of that organ. The speaker did not believe the site of the incision was of essential importance. The abdominal wall at the full term of pregnancy was thin and relaxed easily. As soon as the abdominal incision was made and the uterus exposed, long gauze pads wrung out of warm salt solution were placed within the abdomen to hold back the omentum and intestines and protect peritoneal surfaces while the uterus was being emptied and closed. With the demonstrated results of cesarean section as now obtained, the scope of the operation must necessarily be widened and its application greatly extended. What was most needed at the present time was an active interest on the part of all abdominal surgeons, and such a campaign of education as was successfully applied some years since in behalf of early operation in other conditions requiring prompt surgical intervention. It was established that the primary cesarean operation in skilled hands had a mortality quite as low as uncomplicated ovariotomy and clean hysteromyomectomy. With repeated examinations, cervical dilatation and application of forceps, carried out with crude and desultory observance of aseptic precautions, the mortality of abdominal hysterectomy was necessarily increased. The cooperation of the surgeon and the general practitioner was necessary to correct this fatal error.

Dr. E. Gustav Zinke of Cincinnati stated that if the mortality of cesarean section to-day was too high it was because of carelessness or indifference on the part of those who took obstetric cases and did not give them the attention they deserved. When a woman engaged their services with a view to attending her in her approaching confinement they should study the case carefully. It was here where a mistake was made. Because a woman had a good shape, was otherwise in good health, and there was no indication of any difficulty she was permitted to go until the time of labor had arrived, and the obstetrician in very many instances had not the remotest idea of the capacity of her pelvis or of the position of the fetus within the uterine cavity, and it was because of lack of this knowledge that the woman went into labor, and then labor was protracted from some cause or other, the difficulty of which was detected by the consultant, who saw the necessity of performing hebosteotomy, cesarean section, version, or craniotomy, as the case might be. His sole object in speaking on this paper was to caution the profession anew, and he would do it on every possible occasion, that every case of pregnancy should be thoroughly studied before the woman went into labor. The physician should know all about her pelvis, about the position of the fetus, as well as the condition of her kidneys, heart, liver, etc.

Dr. Ernest S. Lewis of New Orleans said he thought the obstetrician should thoroughly examine every woman whom he expected to confine, not only to determine the presentation of the fetus, but to correct any malpresentation, if it was possible; also to determine the condition of the pelvis by proper mensuration. Statistics showed that cesarean section, the primary operation, was not attended with any more gravity than the removal of an ovarian tumor. He fully agreed with the author of the paper in regard to that, and that the danger was proportionate to the length of time the woman had been in labor, whether examined or not. There was greater danger of infection if frequent examinations had been made or if instruments had been used.

Dr. Reuben Peterson stated if there was one subject in the whole range of medicine that had been neglected in the last twenty years it was obstetrics. This could be explained in a way by the greater pecuniary rewards which had accrued to abdominal and other kinds of surgery, so that it had made the obstetric feature more or less anomalous in this country. Many men graduated from the medical schools without an accurate idea of what to do for a woman during pregnancy, or how to size up a difficult case before labor. The specialist was usually called in after the practitioner had failed to deliver the woman by the natural way. The time was coming when the operation of high forceps would not be taught in the medical schools as an obstetric procedure. High forceps were put on when the head had not entered the pelvic inlet. There was some disproportion between the head and the superior strait, and in his opinion cesarean section gave far better results to the woman and to the child than did the operation of high forceps.

Dr. McMurtry, in closing, stated the attitude of the profession toward cesarean section was a very serious one, and it should be corrected. It was the highest func-

tion of an association like this, whose expressions went out to the profession and were looked upon as authoritative, to correct erroneous impressions, and the erroneous impression he alluded to was the general attitude of the great body of medical practitioners, namely, that cesarean section should not be done until the patient had been examined by two or three men; that these examinations were made with the most perfect observance of asepsis, and all ordinary means of delivery had been tried on the patient for hours. The important point they wanted to impress was to get the great body of the profession to recognize early, if not before labor, early after labor had begun, that it was a case suitable for cesarean section.

Intussusception.—Dr. Stephen H. Watts of Charlottesville, Va., reported two cases of intussusception in the adult, one of which was due to multiple adenomata of the intestine, and the other to a sarcoma of the cecum. In the first case it was found necessary at several operations to perform two resections of the intestine with lateral anastomosis, two other lateral anastomoses, and seven enterotomies for removal of the growths. The patient was perfectly well when seen about a year after the last operation. In the second case, after reducing the intussusception, the sarcoma was removed with an elliptical portion of the wall of the cecum, and the patient made a good recovery. After reporting these cases Dr. Watts discussed in some detail the symptoms, diagnosis, and treatment of adenomata and sarcomata of the intestine.

Complications Due to Operative Procedures.—Dr. L. E. Burch of Nashville mentioned the accidents following operative procedures in his own work, and referred to accidents occurring in the work of other surgeons. He laid stress on the following points: "(1) Many of the accidents following operations were preventable, while others were not. (2) No operation should be advised, however trivial in character, unless there is positive pathology to indicate its performance. (3) No operation should be carried out, either under local or general anesthesia, until a careful history of the case was obtained, including a thorough physical examination, with urinary and blood findings. (4) Better results would be obtained and fewer accidents would happen if patients were given preliminary treatment before operation. (5) Surgeons should never state to patients that any operation was free from danger."

Formation of a New Vagina.—Dr. Alexander Hugh Ferguson of Chicago reported three cases. In the procedure presented the author did not claim to produce a normal vagina, still in two of the three cases reported a vagina had been formed which yielded satisfaction. The third case was not yet married, but there was no doubt but that the vagina would prove as efficient as the other two. The technique of the operation varied slightly in each case, but the underlying principles were the same, namely, first to utilize the available mucous membrane; second, to form three flaps; third, to tunnel through the peritoneum behind the bladder and in front of the rectum, dissecting the peritoneum from both structures without opening the peritoneal cavity; fourth, to invert the flaps into the tunnel thus formed and suture them in place with catgut. The lateral flaps included the mucosa of the labia minora on either side, exercising care not to interfere with the mucous membrane in connection with the clitoris and meatus urinarius. The central flap was cut as thick as possible, in order not to interfere with nutrition. The lateral flaps were cut with the same precaution in mind. The fact that the flaps were not sutured together rendered the cavity dilatable to an ideal extent. Horse hair was used to close over the denuded areas. A roll of gauze about seven inches long was anointed with sterile vaseline and zinc oxide and inserted into the plastic vaginal canal. The external end spread like a flange and was held in place by a firm pad. It must not fit too tightly. As to the after-treatment, the initial dressing must not be withdrawn for six or eight days. The parts must be kept as aseptic as possible. The internal stitches were catgut, and might be left to become absorbed. The horse hair should be left in place for two weeks. Absolute cleanliness without antiseptics was of primary importance. The patient must remain under observation for at least three months.

(To be continued.)

NEW YORK ACADEMY OF MEDICINE.

Special Meeting, Held December 29, 1910.

The President, Dr. John A. Wyeth, in the Chair.

This meeting was held under the auspices of the Section on Dermatology and was devoted to a symposium on leprosy. Several cases of leprosy were presented before the papers of the evening were read.

Historical Sketch of Leprosy in the United States.—Dr. S. Pollitzer read this paper. Leprosy existed in the Orient from the earliest time. It was probably brought into Italy by the soldiers of Pompey in the first century, B. C. It then spread over the greater part of Europe. The notion that the disease was carried by the crusaders into western Europe was without foundation. The disease existed in western Europe long before the crusades. In England the first leper house was founded at Canterbury in 1084, more than ten years before the first crusaders left that country. In Spain the first leper house was founded in 1067. Leprosy increased rapidly; by the end of the thirteenth century there were about 2,000 asylums in France and 200 in Great Britain and Ireland. Then the disease began to decline; at the time of the discovery of America leprosy was, however, quite commonly met with in Europe; while it was evidently on the wane it still existed to a considerable extent during the next two centuries, the period of the colonization of the United States. In view of the relative frequency of the disease in western Europe during the period of the discovery of this country, it seemed remarkable that there was no record of the occurrence of the disease in the early colonial period. One source of leprosy in the United States was the importation of negro slaves from Africa; most of these slaves came from the coast of Guinea and the Niger and Congo Hinterland where the disease was to-day extremely prevalent. The first historical reference to the presence of leprosy in the United States was found in a work published in 1775, "A Concise Natural History of East and West Florida," by Capt. Bernard Romans. At this time the disease existed in Louisiana; it was a matter of record that the disease existed there from the time of the Spanish regime: also that in 1786 the number of leprous beggers in the streets of New Orleans was so large that the authorities took action, and these patients were isolated in a house established for this purpose. This was the first leper house in the United States, and was in use for fifteen years, sheltering forty cases. In Louisiana there had been a notable increase in the number of cases: Dr. Dyer estimated the present number between 300 and 500. In 1815 leprosy was known to have been introduced into New Brunswick by a woman of St. Malo in Normandy; within a few years a number of cases occurred in her immediate family and among neighbors. In 1844 a lazaretto was established for these cases and, up to the present time, there had been about 150 cases in this settlement; this was during a period of nearly a century. About the year 1856 great numbers of Scandinavian immigrants settled in this country, the major portion of them in Wisconsin, Minnesota, Iowa, and Dakotas. Among these there were about 170 lepers: among their descendants it was estimated that there were about 30 cases living to-

day. The Pacific Coast had received a large influx of natives of the Far East and the Pacific Islands. China had from time immemorial been the home of leprosy. San Francisco was one of the most cosmopolitan ports of the world and among its heterogeneous population were lepers from almost every country on the globe. In 1902, 24 living cases were reported. In 1907 Dr. Montgomery reported the histories of 33 cases which he had personally observed since 1891. Within recent years the number of lepers in Texas had assumed notable proportions. In 1902, the Marine Hospital Service reported a total of 278 cases of leprosy in the United States, more than half of these (155) in Louisiana. Of these 176 were males and 102 females. One hundred and eighty-six cases were said to have contracted the disease in the United States. One hundred and forty-five were American born. The foreign born came from Norway (22), China (20), Germany (12), Bahamas (12), Iceland (11), Sweden (8), Ireland (6), West Indies (4), England (3), France (3), Mexico (3), Italy (3), etc. In this report 155 cases were ascribed to Louisiana, 24 to California, 24 to Florida, 20 to Minnesota, 16 to North Dakota, 7 to New York, etc. If Dr. Dyer's estimate of three to five hundred cases in Louisiana was nearer the truth than the official report of 150 cases in that State, and the estimate of 40 cases in New York nearer than the seven given in the report, and a like discrepancy occurred throughout the list, one might conclude that the official record of 278 cases was by far less than one-half the true number of cases in this country. About ten years ago Dr. A. W. Hitt after a careful review of the subject arrived at the conclusion that there were about 530 lepers in the United States and this might be regarded as a conservative estimate.

The Symptomatology of Leprosy.—Dr. Howard Fox said that as the number of lepers in New York City appeared to be slowly but steadily increasing it would seem that a knowledge of the symptoms of the disease was becoming of practical as well as of theoretical interest to the profession of this city. He described the two distinct and classical types, tubercular leprosy, in which the skin and mucous membranes were chiefly affected, and the anesthetic leprosy, in which the nervous system was principally involved. Macular leprosy was described by some writers as a third type; in a few cases the macules constituted practically the only symptom. In most cases, however, they were simply forerunners of either the tubercular or anesthetic stages and need not be discussed as a separate type of the disease. In a large number of cases there was a combination of symptoms constituting what was called the mixed type. Among thirty cases of leprosy that he had seen during the past year Dr. Fox could not recall having seen but one single instance of pure anesthetic leprosy presenting well-marked deformities or mutilation. Cases of pure nerve leprosy were extremely rare. A very early symptom which was observed in many cases, especially of the tubercular variety, was a persistent rhinitis with repeated mild attacks of epistaxis, a very valuable diagnostic sign. If in addition the bacillus could be demonstrated in the nasal secretion an early positive diagnosis could, of course, be made. The first eruption of leprosy might consist of congested erythematous patches that could hardly be considered as characteristic of the disease. After a number of days or weeks this eruption disappeared but might reappear later. After several repeated attacks the macules became permanent or "fixed," their color deepened and did not tend to disappear on pressure. The macules varied in size with borders sharply or poorly defined. They might be hyperanesthetic or itchy at the outset; sooner or later they became anesthetic. The first appearance of the tubercles was often ushered in by febrile symptoms. They might be engrafted upon or appear between the already existing macules. Their surface was greasy and showed as a rule an absence of hairs. The falling of the eyebrows due to tubercular infiltration constituted one of the earliest symptoms of nodular leprosy. They were found in greatest numbers upon the face, imparting to it a peculiar frowning or leonine expression. The scalp seemed to enjoy a remarkable immunity to the ravages of leprosy. The pharynx, palate, uvula, epiglottis, dorsum of the tongue, etc., were sooner or later attacked by diffuse or nodular infiltrations. One of the earliest symptoms of leprosy was a change in the voice. The visual apparatus was frequently involved in tubercular leprosy. The urine contained albumin and casts but no lepra bacilli. In tubercular leprosy the duration of life averaged about eight or ten years. The tubercular leper in the terminal stages of his affliction was an object of pity; the face was distorted by a mass of tubercles, many of them covered with crusts and ulcers; there was a foul discharge from the nose; the voice was lost, sight was destroyed, and the special sense of hearing alone remained. In spite of such a terrible condition, the mind of the leper remained practically unaffected up to the time of death. The outset of anesthetic leprosy might be accompanied by febrile symptoms; it was, however, more apt to appear insidiously and manifest itself by a macular or bullous eruption or by various disturbances of sensation. The symptoms in general of this type were those of a peripheral neuritis causing sensory and trophic manifestations. One of the most important and diagnostic symptoms was an increase in the size of some of the nerve trunks that occurred at a very early period of the disease. At first the nerve trunks were painful to pressure; later they became completely insensible to pain. Sooner or later anesthesia made its appearance and was especially marked in the extremities. At last the anesthesia became so complete that the patient might be able to cut off portions of the hands or feet without experiencing the slightest pain. Atrophy was noted at an early stage in the thenar and hyperthenar regions. The superficial muscles of the face were frequently atrophied. In some cases the process of anesthetic leprosy did not go beyond the production of muscular atrophy and tendinous retraction. In other cases there were bone changes which gave rise to frightful mutilations. The mucous membranes were less often involved in the anesthetic than in the tubercular leprosy. The average duration of life was about fifteen years. The termination of a severe case was pitiful and distressing; the patient was emaciated and cachectic; he was bedridden; the nose was sunken; the sight was lost and saliva poured from the paralyzed lips. He suffered from a sense of cold, insatiable thirst, and severe neuralgic pains. Death was usually due to marasmus, amyloid degeneration of the viscera, or to an intercurrent disease. It was rarely due to pulmonary tuberculosis.

Experimental Leprosy and Its Bearing on Serum Therapy.—Dr. Charles W. Duval of Tulane University, New Orleans, presented this paper, in which he briefly reported some studies upon the biology of and immunity against the bacillus of leprosy, together with a consideration of the possibility of specific treatment and prophylaxis. Soon after the cultivation of the specific organism the possibility of a serum therapy for the treatment of leprosy presented itself, and with this in view Dr. Duval set about to study the blood of lepers. It was thought advisable to first determine whether in cases of human leprosy specific antibodies were present and if so to find out their nature and mechanism of production. The initial growth of the *B. lepræ* cultivation upon artificial medium was in all cases obtained with considerable difficulty unless special methods of cultivation were employed. Leprosy bacilli when freshly isolated from the animal tissues were slightly curved and distinctly headed. In the older cultures the bacilli underwent a decided change in

size, shape, and manner of arrangement. The growth was more rapid and the arrangement was diplobacillary; this diplobacillary arrangement of egg-shaped rods was a characteristic feature for the older cultures. So far he had succeeded in cultivating *B. leprœ* from the cutaneous nodules in eight cases of leprosy, two cases of nasal discharge, and from the experimental lesion in a number of white and Japanese dancing mice and monkeys. The experimental study upon the virulence and viability of leprosy bacilli showed the necessity of early diagnosis and the need of strict segregation of certain types of the disease. The length of time *B. leprœ* would live and retain its infectiousness outside the body indicated plainly the risk to a community in allowing leper patients at large. Especially dangerous were the cases discharging the bacilli in the secretions of the nasal mucous membrane. A house once infected might remain so for years. The results of animal experiments demonstrated the fact that direct communication of the disease might take place from individual to individual without the aid of an intermediate host such as the bedbug or a parasite. The experiments made supported the view that the chief portal of entry for *B. leprœ* to the human body was by way of the nasopharynx. Animal experiments did not tend to support the view that leprosy might reside for years in the human body before manifesting any outward signs of the disease. Direct inoculation from man to man might occur, but it was the exception. Heretofore attempts to infect or produce lesions in animals other than the Japanese dancing mice had been unsuccessful; but of late Dr. Duval had succeeded in producing the lesion in the white mouse, and typical leprosy in the monkey with cultures of *B. leprœ*. Following the cultivation of the organisms his attention was naturally drawn to the possibility of producing an active artificial immunity which might be made use of in the treatment of the disease. In this respect his efforts had been directed along two distinct lines: First, patients suffering from the disease were inoculated with suspensions containing leprosy bacilli and their toxins, and, second, animals had been inoculated with larger doses of the bacilli in the hope of producing to their sera immune bodies which might be used in the passive immunization of human cases. In the examination of blood from patients suffering from leprosy the serum had been shown to contain specific antibodies of different kinds against certain constituents of the *B. leprœ*. Specific amboceptors were undoubtedly present in comparatively large quantities. Not only were specific bodies present in the blood of leprous cases, binding complement with leprosy bacilli, but also substances fixing this body in the presence of phosphatids prepared by the extraction of the human heart muscle. Dr. Duval said that he had been sufficiently impressed by the apparent importance of the specific bodies against the phosphatid fat in the immunization against *B. leprœ* to have undertaken animal experimentation in the hope of preparing a serum of sufficient anti-lipoid potency to be of service in the passive immunization of human cases. The work suggested the prime importance of this phase of the immunity leading to the destruction of the bacillus; this work might be supplemented by the production of either a passive or active immunity against the toxins and protein constituents of the bacillus. He had proved the presence of insoluble toxins against which it was his aim to develop specific bodies, if the greatest advantage in the treatment of the disease was to be achieved. To this end he was continuing the vaccine treatment of cases and proceeding with the attempt to produce an active immunity in animals.

The Sociological Aspects of Leprosy and the Question of Segregation.—Dr. Isadore Dyer of New Orleans read this paper. He called attention to the fact that for over 5,000 years the right of society to control disease had been recognized and that from time to time that right had more or less prevailed in some sort of enforcement. All civilized communities recognized the need of provision for protection against infectious diseases and all, to a greater or less extent, compelled the elimination of the individual as a focus of infection and arrived at this by isolation. Leprosy had always stood as the example of the most fearful of human afflictions. The Biblical estimate of the disease had created a popular horror which even down to modern times had placed the leper as a pariah and a person condemned by his state to abandonment. The ancient walled cities housed these victims of Fate under the worst possible conditions. The record of lazarets in continental Europe in medieval times placed these at some 12,000 and it was not known where the confines of the disease might be placed at that period Until 1850 there was no serious recognition of the disease. With the exception of necessitous asylums in India and other British colonies, occasional lazarets in Japan and the leprosarium in Cuba, no care was taken of those sick with this disease. With the uncounted horde in China to-day compelled to wear the leathern thong and to ring a bell together with the tabulated cases in almost all countries of the world, it was more than likely that leprosy was to-day as prevalent as it ever was and that numerically it was no less. All countries of Europe had made provision for the lepers found; even Russia had asylums. India had systematic care of the lepers themselves as well as of their children. Japan, with her 20,000 lepers, had all of these segregated and in asylums under government care. Norway had reduced leprosy to a controllable condition by systematic methods of segregation, legislation, and registration. Since 1859 the Sandwich Islands had shown considerable interest in leprosy. The Islands of Cuba, Porto Rico, Jamaica, and the Danish West Indies, and of the Mexican and Caribbean Seas had made provision for leprosy. Some South American countries had also made some provision, but this was not general. Mexico had done nothing. The British Government had housed all known lepers at Tracadie, in New Brunswick, and at Darcy, in British Columbia. The United States Government had carried on most praiseworthy methods in the Philippines and in Guam, with hospitals to provide for over 3,000 known lepers. In the United States nothing had been done, however, beyond an abortive attempt at investigation undertaken in 1900. Individual states had taken some notice of leprosy; some had enacted legislation regarding the disease. Iowa, Oregon, and California had laws which were enforced only in California. At the lazaretto in San Francisco there had been from twenty to thirty cases for a number of years; the number being increased from time to time by freshly segregated cases and diminished by the usual deaths and absconders. Massachusetts had a few lepers isolated and cared for near Boston, but no systematic legislation had been enacted. Louisiana alone of all the states had regularly provided for the lepers in the state since 1894. As early as 1878 the Board of Health investigation attracted attention to the prevalence of the disease, and in the year 1890 legislation was first directed at leprosy. They now had a state home where over 200 lepers had been admitted in sixteen years and where at the present time there were about seventy inmates. The neighboring states of Texas and Mississippi had numerous cases for which no provision whatever had been made. The disease had been in existence in these states for over thirty years, and was known to have spread from the earlier cases to those now living in these localities. New cases were arising each year in Louisiana and it was fair to assume that the same process was going on in other states where there were enough cases to act as disseminators of a disease believed to be contagious. Opinion regarding the segre-

gation of leprosy had been well-nigh unanimous excepting in the United States. This view of the disease was taken both at the Berlin Conference in 1897 and the Bergen Conference in 1909. In the face of these facts it was difficult to understand the attitude of the United States and the refusal of the National Congress to entertain the consideration of a national asylum as proposed in the Raynor bill. In the argument for the segregation of leprosy the attitude of the leper should be considered. He realized more than any other the burden of the malady and his frame of mind was at all times introspective. He would be very willing to separate himself from his family and would seek an asylum if this step could be accomplished without the publicity which usually attached to the recognition of this condition by the health authorities. In his usual environment he was morally and physically unable to conduct any sort of systematic care or treatment and was condemned to the inevitable end with the constant dread that at any time one or more of his family might be afflicted with the disease. With the family there was never the supreme sympathy that another disease would engender. The entire household was disorganized and the home of the leper throbbed with unknown dread and fretted with a burden hard to bear. The disease might not be as contagious as tuberculosis or syphilis, but it was still a menace of no mean importance, when it was considered that its spread was as constant as it was insidious and that its evidences were more horrible than most known diseases. For thousands of years it had spread in every country in which it had been introduced. Isolation alone had successfully combated the disease in all times and the experiences in Hawaii and in Norway in the last fifty years had demonstrated this supremely. Segregation meant more than simple separation of the leper from the healthy public; it meant peace of mind, under conditions which made amelioration and even cure possible. Within three months after admission to the Louisiana Leper Home patients began to improve, and this was true of all cases excepting those admitted in the terminal stages of the disease. Leprosy might not be a menace to the United States at the present time, but the increasing numbers of cases and the constantly widening distribution of centers of the disease made it only a question of time when the disease of leprosy would become a menace of no small proportions in this country. National provision should be made for the disease, under conditions that would offer an asylum to all lepers with the hope of intelligent treatment so as to provide for the possibilities of cure. The efforts of all persons interested should be aimed at urging Congress to make provision for such a home. Not all cases of leprosy needed to be segregated. There were lepers who had survived the disease. Such trophic types carried no active signs of the disease and failed to afford any bacillary evidences. These cases should not be isolated as they were beyond any danger to others or relief for themselves.

Dr. Brinckerhoff (late of the Marine Hospital Service, Hawaii) emphasized the necessity for national action with regard to the control of lepers. Was this disease communicable? If so, the question of breaking up the mechanism of its transmission was to be considered. Should not public health officers interfere and attempt to prevent the transmission of the disease? If they were dealing with a communicable disease and if they intended to control it, it was obvious that they should break up the transmission of the disease from the sick to the well. It was to be regretted that they did not as yet know definitely the mode of the transmission of leprosy. The isolation or segregation of these lepers appeared to be necessary. He thought they were justified in using police regulations in controlling this disease by taking away the liberty of the individual afflicted with leprosy.

Dr. White of Boston reported cases of leprosy that had occurred in Massachusetts; this report was obtained from the State Board of Charities. After telling of the laws of that State, he told of the hospital plans they had and the additions they were making to accommodate more patients.

Dr. Schamberg of Philadelphia stated that Pennsylvania had a statute which called for the reporting of leprosy, it being considered a contagious and, therefore, a reportable disease. There they restrained lepers forcibly if necessary. Ten or twelve years ago there was a large number of lepers in the State of Pennsylvania, whereas to-day there were not more than seven or eight. He recalled one indigenous case, a woman about sixty years old, who had never been beyond the confines of the State. Her home had been visited by a sailor who was said to have had elephantiasis. He was in accord with what Dr. Dyer had said regarding the segregation of lepers, but all lepers should not be segregated; there should first be taken into consideration the stage of the disease, the intelligence of the patient, his social status, etc. Every case should be reported. The popular idea of the intense infectiousness and incurability of this disease should be met, and combated. Dr. Schamberg called attention to the laws and tokens whereby the priest was to be guided in discerning leprosy (Leviticus, Chapter XIII) as well as to the rites and sacrifices on cleansing the leper (Leviticus, Chapter XIV). A saner and truer idea regarding the transmissibility of leprosy should be spread, especially by the public authorities; the fear regarding the disease that now existed should be abated.

Dr. Pusey of Chicago called attention to the infectivity of leprosy, especially the difference in this respect between the north and the south. In the north temperate zone there practically were no indigenous cases. According to Hutchinson there were none in London. In Chicago they met with three or four cases a year, and all were immigrants. In this part of the country there was not much danger from leprosy. A leper was potentially dangerous; he was like a live coal thrown into a sand pit. Lepers were comparatively innocuous in this country.

Dr. Prince A. Morrow said that comparatively few cases of anesthetic leprosy in New York City had been seen and the reason was they had escaped observation; personally he had seen many of them. Just how many cases of leprosy existed to-day they did not know; but they knew that a great many more existed to-day than existed fifteen, ten or five years ago. He approved of governmental supervision of the disease; there could be no efficient control of this disease except in this way. There should be, in his opinion, an intelligent discrimination regarding the cases to be segregated. The contagiousness of the disease was greatly modified by climate, the mode of living and other factors. He had seen three or four cases in which the disease was indigenous. He did not believe in passing rigid laws for the segregation of all lepers: in the anesthetic variety such segregation was not necessary because the disease was comparatively innocuous. With regard to the portal of entry Dr. Morrow years ago made the statement that it was through the nasal passages, and he was the first to make such a statement. One woman he had treated remained cured ten years; whether this cure was spontaneous or due to the drugs administered he did not know. The impression that leprosy was an incurable disease should be corrected.

SECTION ON MEDICINE.

Stated Meeting, Held December 20, 1910.

Dr. C. N. B. Camac in the Chair.

The evening was mostly devoted to reports from Bellevue Hospital, Second (Cornell) Medical Division.

A Case of Erythema Multiforme as an Early Manifestation of Tuberculous Meningitis.—Dr. Malcolm Goodrich made this report. An Italian woman, 25 years of age, was admitted to Bellevue Hospital on January 24, 1910. Neither her family nor personal history had any bearing upon her present illness. Two weeks previous to her admission she had noticed an eruption on the cheeks, occurring first as discrete papules and vesicles, which shortly coalesced, forming a continuous patch. The only subjective symptom at that time was slight itching which accompanied the eruption. A few days later numerous bright red spots appeared on the arms and legs, together with several hard raised lumps, which were tender. The appearance of this eruption was accompanied with a feeling of lassitude, anorexia, fever and pains in the joints, especially the knee joints. At the time of her admission to the hospital her temperature was 100.5° F., pulse 96, and respirations 24. She did not look ill. The skin on the cheeks and forehead was red, thickened and scaling. The right pupil was slightly dilated; both pupils reacted promptly to light. Her tongue was coated and the cervical glands were slightly enlarged. Over the extensor surfaces of the forearms, and especially in the vicinity of the wrist joints, there were a number of discrete macules, violaceous in color and irregular in outline, varying in size from a ten-cent piece to a silver dollar. In some of these spots the color disappeared on pressure, while others were distinctly purpuric. There was a similar eruption over the anterior aspects of the tibia and ankles and over the thighs and legs. Having no direct relation to the joints there were noted several raised, sharply circumscribed spots which varied in size and were excessively tender on palpation and urticarial to the touch. The reflexes were normal and there was no effusion into the joints; some tenderness was elicited over the lateral aspects of the knee joints. The blood examination showed hemoglobin 90 per cent., white blood corpuscles, 10,000; polymorphonuclears, 77 per cent.; lymphocytes, 17 per cent; transitionals, 6 per cent. The urinary examination showed a specific gravity of 1034. There was no albumin, sugar nor uric acid. There were a few epithelial cells, white blood corpuscles and hyaline casts. The case was, therefore, one of squamous eczema of the face, an erythema nodosum accompanying an erythema mutiforme of the extremities. During the first three weeks of the patient's stay in the hospital there was no change in her condition. The eczema on the face gradually cleared up. During this time several successive crops of nodes appeared, and on February 18th she said that she felt well and desired to leave the hospital. No new nodes had appeared for several days and the purpuric eruption on the arms and legs was rapidly fading. But one symptom persisted and that was the fever, which continued to range from 99° to 101° F. On February 26 the patient complained of pain in the epigastrium, followed by persistent nausea and vomiting. She became drowsy and apathetic. The ophthalmoscopic examination showed no choking of the discs. During the next week there was total inability to retain food, rapid loss of weight and a temperature varying from 101.5° to 103° F. The pulse was rapid, irregular and of low tension. On March 2 she developed a cough, slight dulness on percussion and high pitched expiration with a few medium moist rales. On March 6 the blood count showed hemoglobin 60 per cent., white blood corpuscles 13,000, polymorphonuclears 74 per cent., lymphocytes 14 per cent. and transitionals 1 per cent. On the following day a spinal puncture was made and seven c.c. of slightly turbid fluid were withdrawn. The laboratory examination was negative for tubercle bacilli and sterile on culture. The patient became extremely restless and assumed the "pointer dog" position. The head was somewhat retracted and the neck rigid. The pupils were irregularly dilated and a moderately convergent strabismus was present. The opthalmoscope showed a double choked disc, but no tubercles of the choroid were observed. The mouth was drawn to the left and the tongue deviated sharply to the left. A marked Kernig sign was elicited. The patella reflex on the left side was absent; it was diminished on the right. The respirations were Cheyne-Stokes in character. The pulse was rapid and weak. Another lumbar puncture was made and 44 c.c. of clear fluid were obtained under considerable pressure. The laboratory report was positive for tubercle bacilli. The patient died on March 10, and the autopsy findings were as follows: Tuberculous lymph adenitis of the cervical and mediastinal lymph nodes, tuberculous bronchitis, and bronchopneumonia involving the right lower lobe, localized miliary tuberculosis of the right lung, tuberculous meningitis, brown atrophy of the heart, parenchymatous degeneration of the kidneys, and otitis media involving the right ear.

Lobar Pneumonia of Micrococcus Catarrhalis and Bacillus Coli Origin.—Drs. F. S. Meara and Walter L. Niles presented this report, which was made by Dr. Niles. He called attention to the report made before the Section on Medicine at its October meeting, 1910, at which a paper on "The Bacteriology of Nontuberculous Infections of the Respiratory Tract" was presented by Drs. T. W. Hastings and Walter L. Niles. (See Medical Record, November 26, 1910, page 984.)

The first case was that of a boy, fourteen years old, who gave a history of having been ill one week with cough and pain in the chest. He had pains in the joints and a sore throat. On admission to the hospital he was in good general condition, with a temperature of 100.8° F., pulse 116, and respiration 28. The examination of the lungs was negative. On the day following his admission the temperature rose to 105° and there were well-marked signs of consolidation of the left lobe. On the ninth day there were signs of consolidation of the right upper lobe; three days later there were signs of consolidation of the right middle and lower lobes. Later the left lobe, which was the first to become consolidated and resolved, again became solid. The patient, of course, was very ill, and had an exceedingly rapid pulse. The leucocyte count was 48,000. The blood cultures examination was negative. The sputum showed cultures of pure micrococcus catarrhalis. After thirty-five days of fever the temperature defervesced. Eventually the patient recovered, showing signs of a well-marked thickening of the pleura, especially at the base of the lung posteriorly. The second case reported was that of a patient thirty-five years old who complained of cough, great prostration, etc.; on admission he had a temperature of 102.8° F. and pulse of 80. The pulse remained slow during the time he was under observation. The respirations were from 24 to 28. Three days after admission he developed signs of consolidation of the right lower lobe. Nine days later he complained of a sore throat, and the Klebs-Loeffler bacilli were found. Then he developed an attack of erysipelas. The leucocyte count was from 21,000 to 23,000. The patient was sent to the Willard Parker Hospital. Three weeks later he was brought back to the hospital (Bellevue). A few medium-sized moist râles were then found. He became edematous as the result of a nephritis. He made a slow recovery and was finally discharged in very good condition, excepting for his nephritis. This patient's pneumonia was of bacillus coli origin.

The Effect of Cold Air on Blood Pressure in Respiratory Affections.—Dr. B. Raymond Hoobler made this report. He told of observations made on children with respiratory affections who were placed out on balconies; in most instances the blood pressure rose from five to ten millimeters of mercury. For instance, one child with a typical lobar pneumonia had a blood pressure one day

which varied from 95 to 110 when indoors; next day when outdoors it varied from 95 to 120. The temperature of this patient was between 103° and 104.5°. Another case was one of pleurisy with effusion, with a moderate temperature; the blood pressure indoors was 110; outdoors it was 130, and this was on a very cold day. When this patient was returned to the ward the blood pressure soon fell to 110. On the following day, when the weather was not so cold, the indoor pressure was 110 and the outdoor pressure 118. A child with incipient tuberculosis with an indoor pressure of 95, when outdoors two hours had a pressure of 105. Other cases were reported and charts were shown illustrating the effects of cold air on blood pressures.

Dr. W. Gilman Thompson said that he had had a similar experience, but the difference in the blood pressure had not been quite so great.

Dr. Henry W. Berg said that the report made was very interesting for the reason that the outdoor temperature seemed to be the determining factor. The effect upon the capillaries of the skin was the important factor in these cases. He regretted that the results from open-air treatment were not encouraging. With this increase in the blood pressure there was as well an increased amount of work placed upon the heart.

Dr. F. S. Meara said that great care was taken with these patients to keep them warm by means of hot bottles; the skin capillaries were not contracted. The patients were kept warm; only their faces were exposed to the cold.

Menus for a High Caloric Diet.—Dr. Warren Coleman presented charts which had formed the basis of the diet for patients with typhoid fever during the past two years at Bellevue Hospital. Milk, cream, and lactose formed the basis of this diet, and the majority of the patients took them without difficulty. He felt justified in making the statement that no typhoid patient should be given less than 3,000 calories. Great difficulty was experienced in striking a nitrogen balance each day in these typhoid cases. There were two things that should be of guide in feeding typhoid fever patients: first, the weight; secondly, their hunger. When they were losing weight the amount of food should be increased; when they asked for food there was no reason why it should not be given. In the early stages of the disease he experienced no difficulty in giving 3,500 or 4,000 calories a day. In reply to the question as to how long this forced feeding should be continued he stated that the patient should not be allowed to lose weight. The weight should be maintained at the point where it stood when he was taken ill.

Dr. Julius Rudisch asked Dr. Coleman why lactose was given in preference to cane sugar; the former was not so well borne.

Dr. Alfred Meyer asked for statistics regarding this forced feeding and its influence on the duration of the disease and its mortality.

Dr. Morris Manges believed that the giving of food which contained 3,000 calories should satisfy all; the freer feeding in cases of typhoid fever was here to stay. In many hospitals it seemed impossible to weigh patients When they complained of hunger they should be fed.

Dr. Leonard Weber never tried to give beyond 4,000 to 5,000 calories to typhoid fever patients, and he only gave feedings every three hours. He gave milk, cream, farinaceous soups, and bread. Later in the disease he ordered soft-boiled eggs and the like.

Dr. Charles E. Nammack said he was not convinced of the value of giving such a large number of calories in the early stages of typhoid fever. This was very difficult to carry out, especially in private practice. The expense of this treatment should be considered.

Dr. Warren Coleman, in answer to Dr. Rudisch, said that cane sugar fermented more rapidly than lactose and produced more tympanitis. With the average patient milk sugar did not ferment so rapidly. He was unable to answer Dr. Meyer's question with regard to statistics. The death rate, however, he believed to be about 3.5 per cent.

Absorption of Fat by Typhoid Patients on High Caloric Diet.—Dr. Eugene F. DuBois gave the results of some experiments of fat absorption in typhoid fever that were made at Bellevue Hospital. He called attention to the experiments of Voit, Rubner, Prausnitz, and others, who showed, some thirty years ago, that the chemical composition of the feces did not vary much when a normal person was put on different diets. The fat in the feces remained about the same though the amount in the food varied greatly. There was an increase, however, in the fat when bacon was fed and when the huge amount of 350 grams of fat in the form of bacon and butter was administered. In the form of butter 214 grams of fat was absorbed. A few years after Rubner's experiments Hoesslein tried the same experiments on typhoid patients. The cases that were almost fasting excreted as much fat as was ingested. The other cases had the normal amount of fat in the stools. This was in spite of a moderately severe diarrhea in all of his cases. Together with Dr. Coleman, the writer had undertaken the examination of the feces of typhoid patients as they came along, without regard to the severity of the infection. All were on the high calorie diet described by Dr. Coleman, and all did well so far as their intestinal condition was concerned. The bowels were emptied daily by an enema, usually soapsuds containing an analyzed amount of soap. The feces were collected in three-day periods, as a rule, the beginning and the end of the periods being marked off by charcoal. Twenty-four-hour specimens of urine were also collected, and the amount of food given was accurately recorded. The feces were dried with the addition of alcohol and the fat content determined by the method of Kumagawa and Suto. Of the four cases investigated one was a case of mild infection, perfectly uneventful; a second was a toxic case with a weak pulse, in which a relapse occurred; the third case had a slight hemorrhage, after which he seemed to be doing well, when he developed a phlebitis and bronchopneumonia, and died; while the fourth case had an infection by one of the members of the typhoid group whose identity was not yet settled. These cases were all on large amounts of fat, as all absorbed it well. Two cases investigated early in the disease showed a somewhat lower absorption than later on. The nitrogen of the feces averaged about one gram; the largest amount recorded was 1.8. From the results obtained from analyses in these four cases they concluded that these cases of typhoid fever were able to absorb fat as well as normal individuals They found that the nitrogen in the feces was not increased above the normal.

Dr. Warren Coleman said that this was only a preliminary report. He called attention to Dr. Jacobi's statement that such patients were only able to take 100 grams of fat in twenty-four hours; they had been able to give from 200 to 360 grams without disturbing the patient's digestion at all.

Dr. J. Finley Bell of Englewood said it was necessary to take into account the character of the fat, *i.e.* the nature of its composition.

Dr. Graham Lusk said that it was very significant to note the application of laboratory methods to hospital practice. They should bear in mind that carbohydrates were the great sparer of proteid; when carbohydrates were burned in the organism proteid metabolism was considerably reduced.

Report of a Case of Glanders.—Dr. W. Gilman Thompson said that, properly speaking, the case was one

of farcy, and not glanders; the nose was not at all involved. The patient was a man, twenty-four years old, and was employed as a mover of furniture. He came in contact with horses. He was ill but a short time when death occurred. His face was very much swollen, and he had a pustular eruption not unlike that of a virulent case of smallpox. Pustules soon appeared all over his body, increased in size, and become hemorrhagic. Each pustule was surrounded by a zone of congestion, and there was a great deal of edema. The temperature was 105° F., and there was a very high leucocyte count. The patient at the end of eight days went into coma and died. Dr. Thompson presented photographs which clearly demonstrated the lesions. It was interesting to note that there were no nasal nor pulmonary symptoms; therefore this was not an inhalation infection. The bacillus mallei was found in the blood cultures, in the urine, as well as in the pustules. Twenty million of the dead bacilli were given, but the patient was too far gone to get any effect whatever. With regard to the frequency of glanders in the Greater City of New York, it was stated that in one year there were as many as 936 cases in horses. Because of the great virulence of the disease it seemed extraordinary that it was not more common.

Report of the Committee Appointed to Investigate the "Infectious Disease of Unknown Origin," as Observed by Dr. Nathan E. Brill.—At the section meeting held on January 18, 1910, Dr. Brill reported upon "An Infectious Disease of Unknown Origin," presenting a symptom complex observed by him in over 250 cases. The section during the year just closed had been engaged in the consideration of the disease, and secured from time to time reports upon the cases observed by members of the section. In order to follow these cases as they appeared in the various hospitals of the city, the chairman of the section appointed the following committee: Drs. John A. Fordyce, S. Lustgarten, W. Gilman Thompson, Warren Coleman, Theodore C. Janeway, Morris Manges, E. Libman, David Bovaird, Jr., J. S. Thacher, and Lewis A. Conner. Every facility for seeing cases, in one of which an autopsy was performed, had been afforded the committee. This committee again met on November 29, 1910. After a general discussion Dr. Fordyce, the chairman, appointed a subcommittee, which reported that the evidence at hand did not seem sufficient to decide whether these cases represented an atypical form of some already recognized disease other than typhoid or paratyphoid fever, or were instances of a disease hitherto unrecognized.

Election of Officers.—*Chairman*, Dr. H. S. Patterson; *Secretary*, Dr. R. H. Halsey.

Intestinal Syphilis.—G. Salomone finds that intestinal syphilis is somewhat rare. It occurs in the form of gummatous deposits which ulcerate and form fistulæ and other lesions in the course of their evolution. The symptoms of these affections are not so characteristic as to make the diagnosis easy. They occur in the tertiary stage of the disease. The author gives histories of three cases observed by him. The lesions in the intestines commence gradually in an obscure and subacute form, and become complicated by other serious lesions of the viscera. Diarrhea profuse, chronic, and rebellious to treatment was a characteristic of all three cases observed. Fever is especially present at night, with headache, profuse sweating, meteorismus, and pain on pressure over the abdomen. The prognosis is dependent on the seriousness of the other visceral lesions. One may have peritonitis, and profuse hemorrhage from amyloid degeneration of the walls of the blood vessels. For a good prognosis two conditions must be present; integrity of the kidneys, and regular function of the cardiovascular apparatus. The duration of the disease is long, covering years. Treatment must be by mercury and iodide of potash used persistently for a long period. Early diagnosis is important for recovery; all the bacteriological and chemical tests are necessary to exclude other intestinal diseases.—*Annali di Medicina Navale e Coloniale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Examiners.

June 13, 14, and 15.

ANATOMY.

1. Give the origin, course, and distribution of the brachial artery.
2. What are the relations of the pneumogastric nerve in the neck?
3. How many bones in a lower extremity? Name them.
4. Name the cerebral lobes and fissures.
5. Give origin, insertion, and action of the triceps muscle.
6. Name the parts of the digestive system.
7. Name the muscles of mastication.
8. Give the blood supply of the stomach.
9. What is the cauda equina, foramen of Winslow, optic thalamus, urachus, canal of Nuck?
10. What difference in the structure of voluntary and involuntary muscular tissue?

PHYSIOLOGY.

1. Describe a cell. How are they propagated?
2. What are the elementary tissues and how are their cells classified?
3. What constitutes the cerebrospinal nervous system?
4. What results are observed when the seventh cranial nerve is paralyzed?
5. What is the relation between blood pressure and the pulse rate?
6. What changes take place in the blood during respiration? Where and how is it accomplished?
7. In a general way, of what does digestion consist?
8. What are enzymes and how do they act?
9. What is the function of the pancreatic juice?
10. What are the solid constituents of the urine and what conditions may change their quantity in health?

CHEMISTRY.

1. How does oxygen give strength to the body?
2. Describe the element that is a part of all acid compounds.
3. What is glycogen, where found, and from what derived?
4. What elements belong to the nitrogen group? Give the properties and uses of the one you consider the most important.
5. What is the amount of CO_2 in the atmosphere, and why does it not increase?
6. In what part of the body and in what forms is phosphorus found?
7. Name the most important elements entering into the composition of the human body.
8. Give the principal constituents of milk. How would you detect water adulteration in milk?
9. What is a poison?
10. Name a poison which has a local and a remote effect and give its antidote.

MATERIA MEDICA AND THERAPEUTICS.

1. Explain the action of heat and cold as therapeutic agents and mention indications for each.
2. Under what conditions would you advise arterial transfusion of blood? What advantage has the process over hypodermoclysis? What disadvantage?
3. Given a case of diphtheria in a child five years old. Describe in detail your treatment and the effect expected of the remedy.
4. When should silver nitrate and when should the organic salts of silver be used in the treatment of ophthalmia neonatorum?
5. Give some indications for the use of thyroid gland. What untoward effects are produced by over-use?
6. Give some indications for the use of arsenic. In what forms may it be used? Give dose of each and symptoms resulting from its excessive use.
7. Outline a diet for a patient suffering with diabetes mellitus. Also, for one suffering with chronic interstitial nephritis.
8. What would you use to overcome pleurisy with effusion? Explain action.
9. Explain the physiological action of the salines.
10. For what conditions would you advise X-ray treatment? How long should the patient be exposed at a single sitting? When would you advise him to return for treatment if a series of treatments were advised?

PATHOLOGY.

1. Name the different kinds of necrosis.
2. Describe the pathology of pyosalpinx.
3. Describe the microscopical appearance of a tubercle
4. Name the different kinds of aneurysm.
5. Define pyemia, septicemia, toxemia, and bacteriemia

DIAGNOSIS.

1. How are functional or hemic murmurs discriminated from organic murmurs?
2. Aphasia and its varieties. What lesions does it indicate?
3. Determine the diagnostic value of laryngeal paralysis.
4. What diagnostic significance is derived from a gross examination of the sputum?
5. What diagnostic significance has coma?

PRACTICE OF MEDICINE.

1. How would you diagnose hereditary syphilis in a child?
2. What are the causes and symptoms of multiple neuritis?
3. Name the symptoms or physical signs of locomotor ataxia.
4. What is apoplexy? Give its etiology and state briefly the symptoms.
5. What is the significance of the Wassermann reaction? How is it obtained?
6. Name conditions with which uremia may be confounded.
7. Give the symptoms and physical signs of thoracic aneurysm.
8. How would you treat lobar pneumonia?
9. Give treatment of epidemic and endemic influenza and give sequela.
10. How would you diagnose and treat cholera morbus?

OBSTETRICS AND DISEASES OF WOMEN.

1. What changes take place in the blood during pregnancy?
2. What purpose do these changes conserve?
3. Give briefly some of the theories which explain how, following labor, the placenta separates from the uterine wall.
4. Give the data upon which at term a diagnosis of first position of the vertex may be made without making a vaginal examination.
5. Name some of the causes which predispose to hemorrhage after labor.
6. You are called at the outset of labor and find a brow presenting; what do you advise?
7. Differentiate between a tubal pregnancy and an acute salpingitis.
8. Name some of the causes and give the treatment of acute cystitis.
9. How would you treat a hematoma of the scalp in the new born?
10. What have you to say concerning chronic endometritis as a cause of sterility? Give its treatment.

SURGERY.

1. Give the diagnostic signs of a typical case of pericardial effusion. What is the treatment?
2. Give the treatment of a fractured costal cartilage.
3. Diagnose a case of gallstones. How treat?
4. Differentiate extrauterine pregnancy, ovarian cyst, and peritoneal effusion.
5. Diagnose anterior luxation of the hip-joint. How correct?
6. Diagnose calculus of the bladder. How treat?
7. Diagnose and give the significance of two kinds of chancre. How treat?
8. How would you treat a case of gonorrheal cystitis?
9. What important structures may be wounded in a vaginal hysterotomy?
10. Differentiate pregnancy and intrauterine fibroid.

DERMATOLOGY, SYPHILOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. Describe ichthyosis and its varieties.
2. How does chronic eczema of the palms of the hands appear and how is it treated?
3. Describe lichen planus (Wilson), its varieties, and mention the treatment.
4. Describe a macular syphilide, or syphilitic roseola.
5. When should the treatment of syphilis be commenced and how should it be conducted?
6. Define hypermetropia; how does it occur, and how is it corrected by lenses?
7. Describe catarrhal conjunctivitis. How is it treated?
8. What is atrophic rhinitis? How is it cured?
9. Describe chronic catarrhal inflammation of the middle ear.
10. Describe perichondritis of the laryngeal cartilages

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

OHIO STATE BOARD OF MEDICAL EXAMINERS.

June 13, 14, and 15.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), page 830; or Gray's "Anatomy" (1908), page 654.
2. See Cunningham's "Anatomy" (1909), page 690; or Gray's "Anatomy" (1908), page 1069.
3. The lower extremity consists of thirty-three bones: Ilium, ischium, pubis, femur, patella, tibia, fibula, os calcis, astragalus, cuboid, scaphoid, internal cuneiform, middle cuneiform, external cuneiform, five metatarsals, and fourteen phalanges.
4. *Cerebral lobes:* Frontal, parietal, temporal, occipital, limbic, olfactory, and island of Reil.
Cerebral fissures: Sylvian, Rolandic, parietooccipital, calcarine, longitudinal, collateral, hippocampal.
5. *Triceps muscle.—Origin:* The long, or middle, head arises from a depression on the axilliary border of the scapula immediately below the glenoid cavity; the external head from the root of the great tuberosity on the posterior surface of the humerus, and the upper part of the musculospiral groove; the internal head from the posterior surface of shaft of humerus, below musculospiral groove, and the internal and external muscular septa. It is *inserted* into the back part of the upper surface of the olecranon process of the ulna. *Action:* It extends the elbow and forearm.
6. *The parts of the digestive system* are: Mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, and ileum), large intestine (cecum, ascending colon, transverse colon, descending colon, and rectum); with accessory parts: salivary glands (parotid, submaxillary, sublingual), teeth, liver, and pancreas.
7. The *muscles of mastication* are: Masseter, temporal, external pterygoid, internal pterygoid, and buccinator.
8. *Blood supply of stomach:* Gastric, pyloric, right and left gastrocpiploic, and vasa brevia arteries and veins.
9. *Cauda equina* is the mass formed at the lower end of the spinal cord by the sacral and coccygeal nerves.
Foramen of Winslow is the narrow passageway between the great and small cavities of the peritoneum.
Optic thalamus is a mass of gray matter at the base of the brain, to the outer side of the third ventricle, and in contact with the internal capsule.
Urachus is a fibrous cord extending from the apex of the bladder to the umbilicus.
Canal of Nuck is a pouch of peritoneum which passes into the inguinal canal in the female.
10. *Voluntary* muscle is striated, has long narrow fibers with cross striations and many nuclei beneath the sarcolemma. *Involuntary* muscle is non-striated, has spindle-shaped fibers, one nucleus centrally located, and no sarcolemma. The great exception is cardiac muscle, which is involuntary and also striated.

PHYSIOLOGY.

1. *A cell* is the ultimate element of structure; it enters into the formation of all tissues. It consists of a tiny mass of protoplasm, and contains a nucleus and an attraction sphere, but as a rule no cell wall. Cells vary in shape and size (from about 1-3000 to 1-300 of an inch in diameter), and are characterized by power of movement, assimilation, growth, excretion, and reproduction.
Cells are reproduced, as a rule, by karyokinesis.
2. The *elementary tissues* are: Epithelial, connective, muscle, and nerve.
KINDS OF EPITHELIUM. (1) *Pavement* or *Squamous:* A single layer of flat, nucleated cells, cemented together at their edges. (2) *Stratified:* In layers of cells that are unlike in form. (3) *Columnar:* Tall, cylindrical cells arranged in a single layer. (4) *Culoidal:* Similar to columnar, but the cells are shorter. (5) *Ciliated:* Columnar cells with hair-like processes (cilia) on their free surface. (6) *Goblet:* Cylindrical cells distended with mucin. (7) *Transitional:* When the cells are neither arranged in a single layer like squamous, nor yet in many

superimposed layers like stratified, but in two or three layers.

Connective tissue cells are: Embryonal, fat, pigment, wandering, plasma, fibrous, elastic, cartilage, and bone. *Muscle cells* are striated and non-striated. (See ANATOMY 10.) *Nerve cells* are unipolar, bipolar, and multipolar.

3. The *cerebrospinal nervous system* consists of: Brain, spinal cord, cranial nerves, and spinal nerves.

4. "When the seventh cranial nerve is paralyzed, the muscles of the face being all powerless, the countenance acquires on the paralyzed side a characteristic, vacant look, from the absence of all expression; the angle of the mouth is lower, and the paralyzed half of the mouth looks longer than that on the other side; the eye has an unmeaning stare, owing to the paralysis of the orbicularis palpebrarum. All these peculiarities increase the longer the paralysis lasts, and their appearance is exaggerated when at any time the muscles of the opposite side of the face are made active in any expression, or in any of their ordinary functions. In an attempt to blow or whistle, one side of the mouth and cheeks acts properly, but the other side is motionless, or flaps loosely at the impulse of the expired air; so, in trying to suck, one side only of the mouth acts; in feeding, the lips and cheek are powerless, and, on account of paralysis of the buccinator muscle, food lodges between the cheek and gums." (Kirkes' *Physiology*.)

5. When the blood pressure in the arteries falls the pulse rate increases; and when the blood pressure rises the pulse rate decreases.

6. The changes which take place in the blood during its passage through the lungs are: (1) the giving up of CO_2 by the venous blood, (2) the absorption of oxygen during inspiration, (3) the blood is cooled, and (4) it also loses a small amount of watery vapor.

These changes occur in the alveoli of the lungs, and are due to both physical and chemical factors, the chief being diffusion; but cell activity may have some part in the process.

7. In a general way digestion may be said to consist of all the changes that occur in food to enable it to be capable of being absorbed.

8. *Enzymes* are substances formed by living cells, which act specifically upon definite substances, and which themselves remain unchanged during this action. Enzymes are generally soluble in water or saline solution; they act best at about the body temperature, and are destroyed by high temperatures; excess of alcohol tends to precipitate them from their solutions; the enzymes can act almost indefinitely, but the products of their activity must be removed.

How enzymes act is not settled; some say by hydrolysis, others, by catalysis.

9. *The functions of the pancreatic juice* are: (1) To change proteids into proteoses and peptones, and afterwards decompose them into leucin and tyrosin; (2) to convert starch into maltose; (3) to emulsify and saponify fats; and (4) to cause milk to curdle.

10. The *solid constituents of the urine* are: Chlorides, sulphates, phosphates, urea, uric acid, hippuric acid, creatinin, xanthin.

In *health chlorides* may be *increased* by muscular exercise, eating, and drinking. *Sulphates* may be *increased* by exercise and meat diet; *diminished*, by vegetable diet. *Phosphates* may be *increased* by exercise, meat diet, mental work, worry, drinking of large quantities of fluids. *Urea* may be *increased* by meat diet and much drinking; *diminished* by vegetable diet, and rest. *Uric acid* may be *increased* by heavy meat diet; *diminished* by vegetable diet. *Hippuric acid* may be *increased* by vegetable diet, *decreased* by meat diet. *Creatinin* and *xanthin* may be *increased* by meat diet.

CHEMISTRY.

1. By oxidation.

2. Hydrogen forms a part of all acids. It is a colorless, odorless, tasteless gas, lightest substance known, is slightly soluble in water, is a good conductor of heat and electricity, does not support life or combustion, but can be ignited, when it burns with a pale blue flame giving an intense heat but very little light.

3. Glycogen is animal starch; it is a white, odorless, tasteless, amorphous powder. It is found in the liver, placenta, white blood cells, muscle, and cartilage. It is derived from glucose by dehydration. $C_6H_{12}O_6 - H_2O = C_6H_{10}O_5$.

4. The answer to this question depends on the textbook used by the student (and examiner). Witthaus groups: Nitrogen, phosphorus, arsenic, and antimony; Bartley groups: Nitrogen, phosphorus, arsenic, antimony, and bismuth; Holland groups: Nitrogen, argon, and helium.

Nitrogen is a colorless, odorless, tasteless gas; lighter than air, slightly soluble in water; it neither burns nor supports combustion; it does not support respiration, and has no tendency to unite directly with other elements; it is not poisonous. It is a constituent of the atmosphere, it is present in nitrates, and is an important constituent of the tissues and organs of plants and animals.

5. The amount of CO_2 in the atmosphere is about four volumes in 10,000. It does not increase, because it is constantly being removed by plants, the chlorophyll of which decomposes CO_2 (under the influence of sunlight) into carbon and oxygen.

6. Phosphorus is found in the brain, nervous tissues, bones, and other tissues; it occurs as phosphates.

7. *Elements entering into the formation of the human body* are: Carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, chlorine, calcium, sodium, potassium, magnesium, lithium, iron, silicon, and fluorine.

8. The *principal constituents of milk* are: Water, proteids (casein and albumin), fat, sugar (lactose), and salts. If the specific gravity of the milk is lowered, and at the same time the total amount of "solids, not fat," is less than 8.5 per cent., it is safe to say that the milk has been watered.

9. A *poison* is a substance which, being in solution in the blood, or acting chemically upon the blood, may cause death or serious bodily harm.

10. Carbolic acid has both a local and remote effect; its *antidote* is sodium sulphates (or other soluble sulphate) and alcohol.

MATERIA MEDICA AND THERAPEUTICS.

1. *Heat*, "locally applied, allays irritation of the peripheral sensory nerves, dilates the cutaneous vessels, increases the secretion of sweat, and probably, like cold and counterirritation, exerts reflexly some influence on the nutrition of the superficial tissues, and even of the underlying organs. Intense dry heat (300° F.—149° C.) not only affects the tissues to which it is directly applied, but also produces general diaphoresis, raises the body temperature two or three degrees, and increases the frequency of the pulse."

"Local applications of *cold* abstract heat from the part, lessen the sensibility of the peripheral nerve filaments, cause constriction of the blood-vessels traversing the tissues exposed to the cold, and affect reflexly the vascularity of parts remote from the seat of the application."

THERAPEUTICS OF HEAT.—"As a local application in many *acute inflammatory diseases*. Generally, it may be used interchangeably with cold, the chief guide in the selection of one or the other being the feelings of the patient Moist heat in the form of fomentations or hot baths is a valuable adjuvant to morphine in relaxing the spasm of unstriped muscles which occurs in *intestinal, biliary* and *nephritic colics*, in *spasmodic croup*, and in *retention of urine*. Hot baths are also useful in breaking up *general convulsions*, especially those occurring in children. Hot footbaths, through their reflex effect upon the circulation, often afford relief in *cerebral congestion, acute coryza*, and *amenorrhea from exposure to cold*. In *acute and chronic parenchymatous nephritis* hot-air baths, hot-packs and hot-water baths are of the greatest service in producing diaphoresis, especially when there is dropsy or uremia. Warm effervescent baths are useful in certain cases of *chronic heart-disease*. The continuous immersion of the patient in a warm bath (90°-100° F.) has been found useful in *extensive burns* and in some cases of *phagedena*. A course of Turkish baths is frequently beneficial in *chronic gout*, in *chronic rheumatism*, and in the early stages of *chronic Bright's disease* and *diabetes*.

"In conditions attended with subnormal temperature, such as *surgical shock* and *collapse from disease* or *poisoning*, the general application of heat, especially in the form of the hot bath, is the most important factor of the treatment.

"The local application of intense dry heat (250°-350° F.) is often very advantageous in certain affections of the joints, especially in *chronic synovitis, traumatic arthritis, sprains, tendinous inflammations*, and in the after-treatment of *fractures* and *luxations*. In *subacute* and *chronic rheumatism* it is also occasionally useful, but in *rheumatoid arthritis* it is of little value."

THERAPEUTICS OF COLD.—"In the early stage of *acute inflammation*, especially that resulting from traumatism, a cold-water dressing often acts most happily. In *diphtheria, scarlet fever* and *acute tonsillitis* the application of cold compresses or of an ice-bag to the throat generally affords

more relief than poultices or fomentations. In *chilblain* or *frost-bite* the intensity of the reaction should be moderated by rubbing the part with snow or ice. In *croupous pneumonia*, when the temperature is high and the pulse strong, an ice-bag or an ice-poultice adjusted over the affected lung reduces the fever, allays the pain, and quiets the patient. In *acute dysentery* ice-suppositories inserted for a length of time, one after another, are very useful in allaying tenesmus. An ice-cap or an ice-bag may be applied to the head with advantage in *meningitis, apoplexy, cerebral congestion, headache*, and the *delirium of fevers*. In *neuralgia* dry cold sometimes affords temporary relief, but, as a rule, heat is more grateful. In *exophthalmic goiter, paroxysmal tachycardia* and *symptomatic palpitation* an ice-bag or a Leiter's coil over the precordia often exerts a sedative influence upon the heart. An ice-bag may also temporarily relieve distress in *aortic aneurysm*, especially when the sac is superficial. In *internal hemorrhage* the application of an ice-bag over the affected region is a useful adjuvant to other measures. Cold bathing is also indicated in *typhoid* and other *continued fevers*."

(From Stevens' *Materia Medica and Therapeutics.*)

2. Under no condition is arterial transfusion of blood to be advised. It has no advantage over hypodermocleisis; the *disadvantages* are: (1) often it is of no use, (2) often it is harmful, (3) clots were often formed which produced emboli in the patient, (4) the blood serum of donor and patient are apt to differ.

3. See French's "Practice of Medicine" (1910), page 195; or Osler's "Practice of Medicine" (1909), page 207.

4. If only one or two applications are to be made, such as in the routine treatment as a prophylactic, a weak solution of silver nitrate may be used. But if frequent applications are to be made, or when used by nurse or family, the organic salts are safer as being less irritant.

5. THYROID GLAND is *indicated* in: cretinism, myxedema, infantilism, simple goiter (*not* exophthalmic goiter), obesity, inoperable cancer, fibroids of uterus, psoriasis, eczema, ichthyosis, puerperal and adolescent insanity. *Untoward effects produced by its overuse:* Nausea, vomiting, headache, restlessness, insomnia, dyspnea, emaciation, pain in back and limbs, anorexia, fever, diarrhea (and symptoms resembling exophthalmic goiter), and death.

6. ARSENIC. *Physiological action:* Escharotic: irritant, tonic; increases cardiac action, respiratory power, intestinal secretions, and peristalsis; produces edema, itching, diarrhea, epigastric pain, irritable and feeble heart. *Therapeutic uses:* In stomach disorders, bronchial and pulmonary affections, diabetes, diarrhea, anemia, and chlorosis, chorea, malaria, and chronic skin diseases.

Official preparations, with their doses: Arseni trioxidum, gr. 1/30; Liquor acidi arsenosi, ♏vij; Arseni iodidum, gr. 1/20; Sodii arsenas, gr. 1/6; Sodii arsenas exsiccatus, gr. 1/20; Liquor potassii arsenitis, ♏vij; Liquor sodii arsenatis, ♏v; Liquor arseni et hydrargyri iodidi, ♏vij. *Symptoms resulting from excessive use:* Anorexia, nausea, indigestion, puffiness of the eyelids, coryza, and diarrhea.

7. See French's "Practice of Medicine" (1910), page 974; or Osler's "Practice of Medicine" (1909), page 420.

8. See French's "Practice of Medicine" (1910), page 715; or Osler's "Practice of Medicine" (1909), page 653.

9. "*Salines* stimulate the intestinal glands to increased secretion, and by their low diffusibility impede reabsorption, causing an accumulation of fluid in the intestinal tract, which, partly from the effect of gravity and partly by gentle stimulation of peristalsis excited by distention, reaches the rectum and produces a copious evacuation." (Potter's *Therapeutics, Materia Medica, etc.*)

10. *X*-ray treatment has been advised for: Epithelioma of skin, lupus, and hypertrichosis. The sittings last about ten or fifteen minutes, and may be renewed every two or three days; but both of these are subject to modification by the expert who is administering the treatment.

PATHOLOGY.

1. *Varieties of necrosis:* Coagulation necrosis, caseation, liquefaction necrosis, fat necrosis, dry gangrene, moist gangrene, and hospital gangrene.

2. *Pathology of pyosalpinx:* "The wall of the Fallopian tube becomes thickened and the muscular layer is hyperplastic. Proliferative changes in the mucous membrane are not unusual, and may lead to polypoid growths. Occasionally small follicular formations are seen in the mucosa; but ulcerations of the mucous membrane are infrequent. When the inflammation extends to the serous coat inflammatory adhesions are frequently formed and may bind the tube firmly to adjacent parts and occasion great congestion or distortion. Very often the abdominal end of the tube becomes occluded by inflammatory adhesions, or by inversion and agglutination of the fimbriæ. At the same time the swelling of the mucosa obstructs the uterine end, and in consequence the tube becomes a closed pouch which fills with pus." (Stengel's *Pathology.*)

3. See French's "Practice of Medicine" (1910), page 342; or Osler's "Practice of Medicine" (1909), page 295.

4. *Varieties of aneurysm:* True, false, sacculated, dissecting, fusiform, diffused, arteriovenous, cirsoid.

5. See French's "Practice of Medicine" (1910), page 208.

DIAGNOSIS.

1. *Organic murmurs* are due to stenosis or incompetency of one or more of the valves of the heart.

Functional murmurs are not due to valvular disease. *Organic murmurs* may be systolic or diastolic; may be accompanied by marked dilatation or hypertrophy, and there will probably be a history of rheumatism or of some other disease capable of producing endocarditis. Whereas a murmur, usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, is a *hemic* or *functional* murmur, and denotes as a rule an impoverished condition of the blood.

2. See French's "Practice of Medicine" (1910), page 1141; or Osler's "Practice of Medicine" (1910), page 955.

3. *Laryngeal paralysis* may be due to "central nervous lesions, as bulbar paralysis; peripheral nervous lesions, affecting the recurrent laryngeal nerve (such as aortic aneurysm, tumor of mediastinum, diphtheritic paralysis); local lesions of the vocal cords (such as ulceration due to syphilis, or tuberculosis); and hysteria."

The nerves involved are the superior laryngeal and the recurrent laryngeal (both branches of the pneumogastric nerve).

The following oft-quoted table from Glowers shows the symptoms, laryngoscopic picture, and lesions:

SYMPTOMS.	SIGNS.	LESIONS.
(*a*) No voice; no cough; stridor only on deep inspiration.	Both cords moderately abducted and motionless.	Total bilateral palsy.
(*b*) Voice low-pitched and hoarse; no cough; stridor absent or slight on breathing.	One cord moderately abducted and motionless, the other moving freely and even beyond the middle line in phonation.	Total unilateral palsy.
(*c*) Voice little changed; cough normal; inspiration difficult and long, with loud stridor.	Both cords near together, and during inspiration not separated, but even drawn nearer together.	Total abductor palsy.
(*d*) Symptoms inconclusive; little affection of the voice or cough.	One cord near the middle line, not moving during inspiration; the other normal.	Unilateral abductor palsy.
(*e*) No voice; perfect cough; no stridor or dyspnea.	Cord normal in position and moving normally in respiration, but not brought together on an attempt at phonation.	Adductor palsy.

—(From Hughes' *Practice of Medicine.*)

4. *Sputum* may vary in its several characteristics according to the morbid condition present. *Mucoid sputum* is glairy, clear, and tough and contains considerable mucin. It may be observed in health but occurs with great frequency in the early stages of acute bronchitis, pneumonia, and phthisis, in asthma, and in pulmonary edema. *Watery or serous sputum* occurs in pulmonary edema and is frothy in character. *Mucopurulent sputum* is made up of varying proportions of mucus and pus. It is encountered

usually in subacute and chronic bronchitis, pneumonia in the stage of resolution, and phthisis. *Purulent sputum* is that which is made up almost entirely of pus. This is a rare condition and occurs in abscess of the lung, or adjacent viscera discharging into a bronchus, tubercular cavities, bronchiectasis, and empyema. *Nummular sputum* is that variety which occurs in round, flat disks which sink when placed in water; when spherical it is termed *globular sputum*. It accompanies advanced tuberculosis and bronchiectasis. *Fetid sputum* is that which when allowed to rest undisturbed separates into three distinct layers; the upper layer being composed of a frothy, watery material; the middle layer being made up of a greenish mucoid substance; and the bottom layer consisting of pus and débris. It is a symptom of gangrene of the lungs, bronchiectasis, and advanced cavity formation. *Fibrous sputum* contains many fibrous shreds and may be seen in the various inflammations attended with fibrin formation, as fibrinous bronchitis, diphtheria, etc. The *rusty sputum* is a form encountered in lobar pneumonia, of which it is characteristic. It is due to the admixture of a small quantity of bright fresh blood with the thick, tenacious mucus present. When the blood is retained in the vesicles and bronchioles it becomes altered and forms the *prune-juice sputum*. In gangrene, cancer, and low forms of croupous pneumonia it may be observed. A further degeneration of the blood in the lungs as in malignant disease gives rise to the production of *currant-jelly sputum*. The sputum observed in hepatic abscess contains blood, pus, bile elements, and amebæ, and is called *reddish-brown sputum*."—(Hughes' *Practice of Medicine*.)

5. *Diagnostic significance of coma:* "Coma occurring very suddenly is characteristic of apoplexy, catalepsy, and sunstroke. More or less complete, and making its appearance gradually, it may attend any of the fevers and acute infectious diseases, as typhoid, typhus, and pernicious malarial fevers. It is also a symptom of narcotic poisoning, as from alcohol, chloral, opium, ether, chloroform, nitrous-oxide gas, and coal gas. It is also caused by uremia and late in the disease by diabetes; also by septicemia, pyemia, carcinoma, acute yellow atrophy of liver, and asphyxia. Injuries to the head, which involve concussion or laceration and pressure upon the brain; any organic, inflammatory, or hemorrhagic disease of the brain; disease of the cranial bones, meningeal hemorrhage or tumor, abscess or tumor of the brain, cerebral syphilis, thrombosis, or embolism, softening, general paresis, and multiple sclerosis may also be attended with coma."—(From Butler's *Diagnostics of Internal Medicine*.)

PRACTICE OF MEDICINE.

1. See French's "Practice of Medicine" (1910), page 432; or Osler's "Practice of Medicine" (1909), page 269.
2. See French's "Practice of Medicine" 1910), page 1014; or Osler's "Practice of Medicine" (1909), page 999.

4. See French's "Practice of Medicine" (1910), page 1107; or Osler's "Practice of Medicine" (1909), page 966.
5. The *Wassermann reaction* is said to be diagnostic of syphilis. "In this test a watery extract of syphilitic fetal liver is used as the antigen to fix the syphilitic immune body present in the serum, and the hemolytic system is arranged as follows:

"The serum from the patient previously inactivated by heating (therefore only containing immune body), mixed with liver-extract and a small quantity of fresh serum (to provide the complement), is incubated at 37° C. for one hour; to it are then added sensitized red cells (that is to say red cells mixed with their appropriate, but inactivated, hemolytic serum) and the mixture is again incubated for two hours at 37° C., removed to an ice chest, and allowed to stand for twelve to eighteen hours before examination. A similar hemolytic system is put up at the same time to act as a control, in which the suspected serum is replaced by that from a normal individual. If syphilitic antibodies are present in the suspected serum, no hemolysis will take place, as the complement required by the sentitized red cells for this reaction to occur will have been already utilized and bound by the syphilitic immune body to the lipoid of the liver extract. This constitutes a positive reaction. In the absence of immune body from the suspected serum, however, complete hemolysis will take place and a negative reaction is recorded."—(Bosanquet and Eyre's *Serums, Vaccines, and Toxines*.)

OBSTETRICS AND DISEASES OF WOMEN.

1 and 2. See Williams' "Obstetrics" (1909), page 172; or Hirst's "Obstetrics" (1909), page 185.
3. See Williams' "Obstetrics" (1909), page 292; or Hirst's "Obstetrics" (1909), page 435.
4. See Williams' "Obstetrics" (1909), page 255; or Hirst's "Obstetrics" (1909), page 395.
5. See Williams' "Obstetrics" (1909), page 818; or Hirst's "Obstetrics" (1909), pages 585 and 586.
6. See Williams' "Obstetrics" (1909), page 284; or Hirst's "Obstetrics" (1909), page 416.
7. In *tubal pregnancy* there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *salpingitis* there are no signs of pregnancy, the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), backache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender.
8. ACUTE CYSTITIS. (*a*) *Etiology:* Various pathogenic bacteria, foreign bodies, traumatism, retention of urine, unclean catheters, cold. (*b*) *Treatment* includes: Rest, administration of plenty of cold water or milk, diuretics, bland and mild food, laxatives, hot sitz baths or vaginal douches, irrigation of the bladder with antiseptic solution followed by solution of nitrate of silver.
9. *Treatment of hematoma of the scalp in the new-born:* It should be protected from injury and a soothing lotion may be applied. No other treatment is necessary unless suppuration occurs, when it should be opened.
10. "*Endometritis* has been said to be a cause of sterility It is a word used so loosely that no one can tell without description what anyone means by it. There is no evidence that it has any effect upon fertility. Papers have been writen about the cure of sterility by curettes, cauterizing, etc., but none contain any presentation of evidence in a scientific form. In most cases supposed to have been thus cured either there was no presumption of sterility or the dilatation of the cervix was the actual curative agency."—(Herman's *Students' Handbook of Gynecology*.) The *treatment of chronic endometritis* consists in removing any pathologic condition that may be found: often curettage and irrigation will help.

SURGERY.

1. See French's "Practice of Medicine" (1910), pages 569, 570, and 573; or Osler's "Practice of Medicine" (1909), pages 779, 781 and 783. For *treatment* see also Rose and Carless' "Surgery" (1908), page 931; or Da Costa's "Surgery" (1908), page 305.
2. See Rose and Carless' "Surgery" (1908), page 493; or Da Costa's "Surgery" (1908), page 477.
3. See Rose and Carless' "Surgery" (1908), pages 1059 and 1061; or Da Costa's "Surgery" (1908), pages 891 and 894.
4. For diagnostic points of *extrauterine pregnancy* see above, OBSTETRICS AND DISEASES OF WOMEN, Question 7; the other two conditions are shown in the following table from Dudley's *Gynecology:*

ASCITES.	OVARIAN CYST.
1. Previous history of visceral disease.	1. No such history
2. Enlargement comparatively sudden.	2. Gradual.
3. Face puffy; color waxy; early anemia.	3. Facies ovarian Anemia absent, or later.
4. Patient on back; enlargement symmetrical; flat in front.	4. Asymmetrical until tumor is quite large; prominent in front.
5. Sitting up, abdomen bulges below.	5. No appreciable change.
6. Navel prominent and thinned.	6. Navel usually unchanged

ASCITES.	OVARIAN CYST.
7. Fluctuation decidedly clear, diffuse throughout abdomen, but avoids highest parts in all positions, and always has a hydrostatic level.	7. Less clear; limited to cyst; not modified by change of position. No hydrostatic level.
8. Intestines float on top of fluid; hence percussion gives clear tympanitic note over the highest parts of abdominal cavity, and dullness in lowest parts for all positions, *i.e.* areas of resonance and dullness change with position.	8. No change in areas of dullness and resonance with change of position. Dullness over cyst. Clear resonant note in all parts beyond cyst limits, *i.e.* in flanks and toward the diaphragm.
9. Vaginal touch detects fluctuation, bulging into vagina.	9. Vaginal fluctuation less clear or absent.
10. Uterus in prolapsed location, but position unchanged. Size and mobility unchanged.	10. Uterus displaced forward or backward, or laterally by pressure of cyst.
11. Hydragogues and diuretics temporarily remove the fluid.	11. Medicines have no effect.
12. Fluid light straw color and thin. Coagulates spontaneously.	12. Fluid light or dark and of varying consistency; albuminous, but does not coagulate spontaneously; may contain colloid mater.

—(From Dudley's *Gynecology*.)

5. See Rose and Carless' "Surgery" (1908), page 632; or Da Costa's "Surgery" (1908), page 603.

6. See Rose and Carless' "Surgery" (1908), pages 1214 and 1215; or Da Costa's "Surgery" (1908), pages 1132 and 1134.

7.

CHANCRE.	CHANCROID.
First lesion of a constitutional disease, viz., syphilis.	A local disease.
Due to syphilitic infection.	Due to contact with secretion from chancroid.
Generally a venereal infection.	Always a venereal infection.
May occur anywhere on the body.	Nearly always on genitals.
Period of incubation never so short as ten days.	Period of incubation always less than ten days (generally about three).
Generally single.	Generally multiple.
Not autoinoculable.	Autoinoculable.
Secretion slight.	Secretion profuse and purulent.
Slightly or not at all painful.	Generally painful.
As a rule only occurs once in any patient.	May reoccur in same patient.
Buboes are painless and seldom suppurate.	Buboes are painful and usually suppurate.

For treatment, see Rose and Carless' "Surgery" (1908), pages 157 and 141; or Da Costa's "Surgery" (1908), pages 288 and 1180.

8. See Rose and Carless' "Surgery" (1908), pages 1192 and 1193; or Da Costa's "Surgery" (1908), page 1164.

9. The bladder, ureter, intestine, uterine artery.

10. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. "*Ichthyosis* is a congenital, chronic deformity or hypertrophic disease of the skin, characterized by dryness, harshness, or general scaliness of the skin, or in the outgrowth of large masses of a corneous consistency. *Varieties* are: Ichthyosis simplex and Ichthyosis hystrix.

"*Ichthyosis simplex* is the more common variety, consisting of a harsh, dry condition of the whole surface, accompanied by the production of variously sized and shaped reticulated scales, either small, thin, and furfuraceous, like bran, or large and thick, resembling fish scales. Upon the extremities the scales usually form diamond-shaped or polygonal plates, separated from one another by furrows or lines which extend down to the normal skin. In color, the scales are either whitish, grayish, or yellowish, and often have a silvery or glistening appearance. Rarely the color is olive-green or blackish (*ichthyosis nigricans*). The amount of scaling depends upon the age of the patient and the duration and severity of the disease.

"*Ichthyosis hystrix:* With or without the development of the above variety, in this the hypertrophy of the skin may occur in circumscribed patches or large areas, consisting of irregularly shaped verrucous, corneous, corrugated, wrinkled, or rugous masses, usually darker in color than those of the simple variety. They may occur upon the arms, as solid, warty patches, or upon the back, in the form of elongated, linear patches. They may constitute roughened, corrugated, papillary growths, or even horny, blunt, or pointed, spinous, warty formations. In the latter case the elevations may reach several lines or more, and stand out from the skin like quills upon the back of a porcupine—hence the name hystrix. The amount and extent of the hypertrophy vary; the older the patient the more highly developed it will usually be."—(From Hughes' *Practice of Medicine*.)

2. The *symptoms of eczema of the palms of the hands* are: Infiltration, thickening, callosity, moisture followed by dryness, and fissuring, the last named frequently becoming so deep and painful that the patient is unable to use his hands. The affection is always chronic, and itching is a constant and annoying symptom. *Treatment:* First macerate the skin with hot water, then rub in the following ointment:

℞. Hydrargyri oleat. 5-15 per cent., ʒiv
Olei cadi ni, f℥ss.
Cerat. simplicis, ʒiv.

3. LICHEN PLANUS is a chronic inflammatory disease of the skin characterized by small, flat, angular, umbilicated, glazed, reddish papules, accompanied by intense itching. The eruption may appear suddenly or gradually, and usually appears on the extremities. The lesions vary in size from a pinhead to a pea, and tend to occur in patches which often assume a linear form. The papules are flat, angular, glazed, slightly umbilicated, and of a reddish or violaceous color. As the affection progresses scales form on the lesions. Itching is marked. After the eruption subsides, the sites of the lesions remain pigmented for an indefinite period. *Varieties:* Lichen ruber acuminatus and Lichen scrofulosus. *Treatment:* Internally; remedies such as arsenic, iron, quinine, strychnine, and cod-liver oil should be administered. Rest is of value. The diet should be regulated and the personal hygiene should receive attention. Locally, lotions and ointments containing antipruritics should be employed. Tar, mercury, salicylic acid, menthol, and carbolic acid are useful in this connection.—(From Hughes' *Practice of Medicine*.)

4. See Rose and Carless' "Surgery" (1908), page 149; or Da Costa's "Surgery" (1908), page 280.

5. See Rose and Carless' "Surgery" (1908), page 155; or Da Costa's "Surgery" (1908), page 288.

6. *Hypermetropia* is that condition of the eye in which the axis of the eyeball is too short, so that parallel rays are brought to a focus behind the retina. It may be congenital, and due to lack of development of the eye. It is treated by convex spherical lenses, which bring parallel rays to a focus on the retina (instead of behind it).

7. *Catarrhal conjunctivitis:* The conjunctiva is swollen and red, there is increased secretion (mucoid or mucopurulent); the eyelids itch, and feel hot and heavy; photophobia is present. Iced compresses may be applied, or boric acid or salt solution; vaselin may be applied to the edges of the lids to prevent them from sticking together.

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Contagion of Syphilis by Means of Drinking Cups.—A. Fournier cites some experiments made with a view to ascertain the part that the communion cup may play in spreading syphilis, tuberculosis, and other diseases. Twenty-seven persons having pulmonary tuberculosis were made to drink out of the same cup. The edge was then wiped with a sterilized tampon of cotton, and this was introduced into the abdominal cavity of a guinea pig, which died of generalized tuberculosis, as was shown by autopsy. Again five persons having tuberculosis drank from one cup. This was wiped carefully with a towel. Sterilized tampons were then used to wipe the edges, and they were introduced into the abdomen of a guinea pig, and it also died of tuberculosis. The wine left in the cup after tuberculous persons had drunk from it was analyzed, and it was found that several kinds of bacilli were in it, among them staphylococcus pyogenes, which caused staphylococcic infection in twenty-four hours. These came from the moustache and lips of the patients. It is easy to see from these conclusive experiments how much harm may be done by the indiscriminate use of drinking cups in causing syphilis and other contagious diseases.—*Journal de Médecine de Paris.*

Chronic Obstetrical Inversion of the Uterus Treated by Posterior Colpohysterectomy.—Blanc and Wies give the histories of two cases of chronic inversion of the uterus which were treated by posterior colpohysterectomy, with recovery in one and death from infection in the other. This complication may result from the presence of tumors at the fundus, or improper manipulations undertaken during delivery. When the placenta is under removal traction on the cord or pressure on the fundus combined with inertia uteri may result in the inversion When acute it may cause death at once with great pain and from severe hemorrhage. It may be accompanied by less marked symptoms and may become gradually complete and remain so, becoming chronic. The result is an infection which will rapidly cause death if reduction is not effected. Spontaneous reduction is rare. In general it is necessary to reduce it by manual means, or by tamponing with iodoform gauze after partial reduction, or to remove it before infection has become general. The best operation for its cure is colpohysterectomy unless the woman is young. In the latter case hysterectomy by the extravaginal method of Pinard is to be preferred.—*Gazette de Gynécologie.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of January 21, 1911.

	Cases	Deaths
Tuberculosis Pulmonalis	594	161
Diphtheria	334	36
Measles	321	11
Scarlet Fever	465	12

ELECTROCARDIOGRAMS AND THEIR SIGNIFICANCE.*

By THOMAS E. SATTERTHWAITE, M.D.,

NEW YORK.

Last summer I spent a good part of six weeks in Franzensbad, seeing the Einthoven electrocardiographic machine operated by my friends, Dr. Edmund Hoke and Dr. Theodor Wohrizek. What I thus learned serves as a basis for the short paper I now present.

Muscle tissue, in the performance of its functions, evokes three things: (1) Animal action or motion; (2) Animal warmth; (3) Animal electricity. The first of these is, of course, the most important to the economy. As compared with it, the production of animal warmth and electricity are insignificant.

Now, the discovery that electrical currents emanate from contracting muscular tissue was foreshadowed by Harvey when he published his "Exercitatio Anatomica de Motu Cordis," etc., in 1628. But Matteuci in 1843 was apparently the first who actually demonstrated it, confirmation coming from Kölliker and Remak, independently, in 1850. During the last ten years no less than sixty individuals have made a study of it, while, according to a list of references in Kraus and Nicolai's recent book, "Das Electrocardiogram" (1910), no less than twenty-five have written on electrocardiography. The reason for this great activity is to be found in the importance of utilizing electricity for commercial purposes; otherwise, electrographic methods would not have been brought so rapidly to their present standard of efficiency. In fact, it was Ader's registration machine, as applied to submarine cable work, brought into notice in 1897, that led to the construction of the string galvanometer which is an essential element in the electrographic machine. For the one most in favor, made by Edelmann and Son, of Munich, utilizes the Einthoven or string galvanometer. It should be stated parenthetically, however, that Lippmann, in 1873, by his invention of the capillary electrometer, had already furnished the idea of a hypersensitive capillary electrometer.†

The idea of registering the action of heart muscle depends upon the fact that there is a ratio between the contracting force of certain heart muscles and the current that emanates from them. This fact was discovered by H. Waller of England as early as 1887. Putting it in another way, electrical currents are to some extent measures of the muscular action of the heart's chambers. This does not militate against another fact, that some muscular contractions are not always shown by electric equivalents on the sensitive paper of the Einthoven machine. For faulty manipulation of the apparatus may, in some instances, explain this omission.

Now, as already said, Matteuci discovered in 1843 that electromotive force emanated autochthonously from the heart. DuBois Reymond confirmed this discovery in 1849 by the use of a very delicate galvanometer. Remak and Kölliker following, as already stated, in 1850. Müller and Kölliker showed later (1850-1856) that there was a special current developed in the auricles during their contraction.

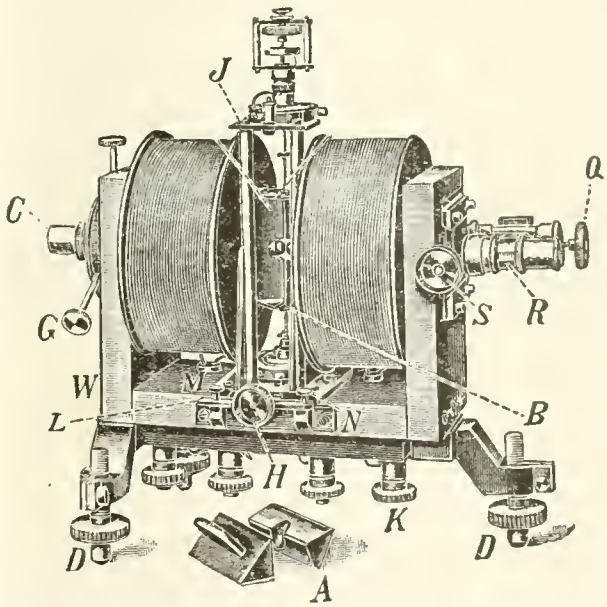

Fig. 1.—The Einthoven galvanometer electromagnets and microscope.

Lippmann, however, in 1873, appears, in addition to his invention of the capillary electrometer, to have been the first to devise a registering apparatus, though Marey of Paris subsequently made a very good recording instrument. The latter was able to throw the shadow of a moving column of mercury on an open space behind which was a moving sensitive plate upon which were photographed the oscillations of the column. But Marey's work was overlooked. Between 1887 and 1889 Waller was developing his capillary electrometer that registered the heart's action. Altogether it has taken two-thirds of a century to complete the Einthoven machine of the present day.

For the string galvanometer is the standard instrument, and that of Einthoven of Leyden is the one in general use. Ader used at first a capillary

*Read at a meeting of the Medical Association of the Greater City of New York, held in the Borough of The Bronx, January 9, 1911.

†Dr. J. B. Stein of the College of Dentistry has for some years been in the habit of using this electrometer in his demonstrations of cardiac action in the lower animals.

galvanometer made of fine copper or aluminum wire which was suspended at right angles to the poles of a permanent magnet. He used a wire as much as 100 cm. long, in order to have large excursions. The diameter of the wire was about 2/100 of a millimeter.

Ader, in 1897 (*Comptes Rendus de l'Acad. des Sc.*, vol. 124, p. 1440, 1897), devised his instrument, known as Ader's receptor, to supersede those of Thomson (Lord Kelvin), known respectively as the mirror receiver and the siphon recorder. By the mirror method the electric current passed through

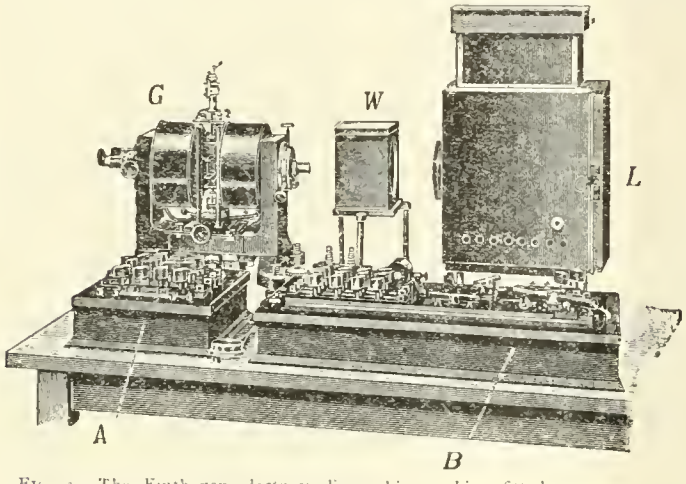

FIG. 2.—The Einthoven electrocardiographic machine fitted to a table.

a large coil within which was a copper tube containing a magnetized needle hung by a short thread before a mirror. The needle oscillated under the action of the currents, and the operator sitting before the mirror read the dispatch as he would read the Morse alphabet. This instrument has, however, been superseded by the siphon recorder, used very largely at the present time by the transatlantic Commercial Cable Company of this city. It was invented by Thomson in 1867 (*Bright's Submarine Recorder*, p. 630).

The siphon recorder apparatus consists of a very light coil of wire suspended between the two poles of an electromagnet, and capable of turning on its vertical axis. According to the direction of the current, the coil turns one way or the other. The motion of this coil is transferred to a capillary glass siphon, one end of which is bathed in ink while the other is approximated to a slip of paper moved by clockwork. The ink being connected with a small electrostatic machine and the paper with the earth, the ink is attracted to the paper, and issues from the capillary tube with a rapid succession of spurts. When the siphon is at rest it writes a straight line on the moving paper—in this instance a tape—but when actuated by positive and negative currents it oscillates from one side to the other, and the deviations above and below an imaginary line correspond to the dots and dashes of the Morse code. An operator reading the marks on the paper, as they pass by clockwork before him, converts them at once, on the same paper, into the Morse code, while another operator sitting opposite reads the Morse message and simultaneously typewrites it into the ordinary message.

Now, in the Ader recorder a long vertical wire, through which the current passes, is stretched in a magnetic field, and is drawn from side to side by the poles of the magnet, while a ray of light from a lamp throws the shadow of a minute portion of the moving wire on a moving strip of photographic paper in the form of an undulatory dotted line. This method has been used extensively by some of the French submarine cable companies, while the Einthoven machine is an adaptation of it for electrographic work in heart disease.

But Einthoven, the inventor, and Edelmann, the manufacturer, have improved on the Ader galvanometer. Einthoven's is now usually made of silvered quartz. Other instruments to accomplish a like purpose are made in Cambridge, England, by the Cambridge Scientific Instrument Company, by Wertheim-Solomonsen of Amsterdam, by Lorenz of Berlin, and by Kunsch and Jaeger of Rixdorf. The poles of the magnet are perforated and illuminated, and the galvanometer, suspended at right angles to the perforations, is charged by the current of the magnetic field, while a portion of the shadow of the vibrating wire, magnified by a microscopic lens, is thrown on the moving sensitive plate and photographed.

As the open space is a very narrow slit and the wire is at right angles to it, the shadow thrown on the paper is that of a minute quadrilateral. Now, this little quadrilateral, a mere speck, vibrates back and forth, throwing its shadow on the moving plate, the successive vibrations corresponding to the particular cardiac muscle that contracts. The greatest contraction, which is that of the ventricles, forms the high notch in the tracing; the smaller notch that precedes the bigger one is the contraction of the auricles. The tracing does not distinguish between the right and left ventricles, or right and left auricles, but records the sum of the contractions of the two ventricles and two auricles. These are the main characteristics of every tracing. There are subordinate notches to be described later.

The electromagnets, constituting the north and south poles, are fed by an accumulator battery of about ten volts, which is a necessary part of the

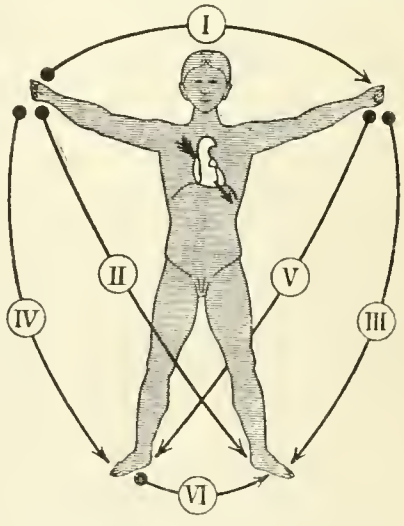

FIG. 3.—The six leads. Kraus and Nicolai.

outfit. The principle on which the galvanometer works is that an electric conductor actuated by a current placed in a magnetic field at right angles to the magnetic current oscillates forward and backward, according as the current is ascending or descending, as with the oscillating current of the

street supply. The amount of oscillation depends on the strength of the magnetic field, the strength of the street current, and the resistance.

But besides the accumulator battery, the machine requires a "null" apparatus. For when the hands or arms or feet are immersed in salt water, a so-called "null" or body current develops, and it has to be eliminated or "compensated for" in some way. Accordingly, on the table of the machine there is a "null" apparatus, or "condenser," which must be placed in the line of the electric current.

Another apparatus to be fitted to the table is an appliance for regulating the voltage or amperage. Wheatstone's bridge is also used in addition for estimating the resistance of the electrodes and the body of the patient.

In Fig. 1 is seen an Einthoven galvanometer (J), suspended between the poles of two electrodes. The electromagnets are wound with copper wire, and set in an iron frame (W), supported on adjustable feet (D D). A microscope (R) pierces the axis of the magnets, and is illuminated by a lighting appliance (C). An apochromatic lens is fitted into the tube R, and another into the tube C. The first magnifies, and the second casts the shadow on the sensitive plate, operating through a narrow cleft which causes the shadow in the form of a minute right-angled speck to write on the plate as it vibrates back and forth. It is no easy matter to throw the shadow on the paper. Careful adjustments have to be made of the micrometer screws (L and Q), so as to throw the shadow into the middle of the field, while the adjusting micrometers (G and F) have to be turned until all color defects have been eliminated. The plugs (A A) are used to shut off light currents of air, etc., that might disturb the electric currents.

Accordingly, for heart work, there is needed to make the apparatus complete: (1) A string galvanometer; (2) a lamp; (3) electrodes; (4) an accumulator battery; (5) an apparatus for testing the susceptibility of the galvanometer; (6) an apparatus for compensating the "null element"; (7) a photo-registering apparatus; (8) an achromatic microscope.

In Fig. 2 there is seen at L an electric arc lamp, the intensity of the flame being regulated by adjusting screws. At W is seen the water bath used to absorb the heat rays of the lamp. At G is the galvanometer suspended between the poles of the magnets. Alongside of these are the accumulator batteries, while under the lamp and water bath are the "null" apparatus and the apparatus for testing the sensitiveness of the galvanometer.

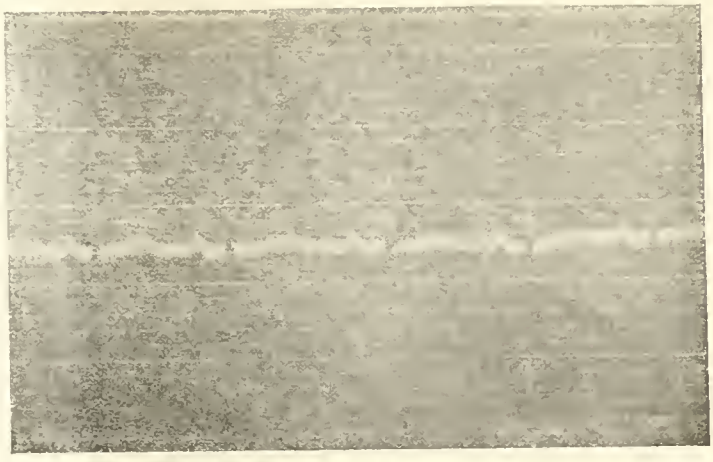

Fig. 6.—Electrocardiogram in a case of aortic aneurysm, as shown by the Röentgen ray, with clinical signs of aortic and mitral insufficiency. There is seen to be moderately strong initial contraction of the ventricles, but well pronounced contraction of the auricles. The final contraction of the ventricles is not well marked, but the rhythm is fairly good. (Franzensbad, August 10, 1910.)

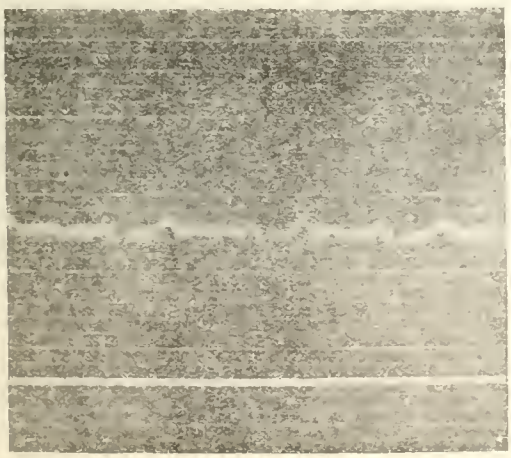

Fig. 5.—Electrocardiogram of a normal heart taken by a lead through the right arm and left leg. A 1,000 volt current and a 1 cm. excursion of the needle on the screen were employed. This tracing was taken in the laboratory of the Mechanicophysical Institute of Franzensbad, during the past summer (1910).

Now, as a matter of fact, the course of the electric current generated in the muscles of the cardiac chambers is much like that of the currents that pass over the surface of the heart, as to direction. We know that the left ventricle and right auricle are the heart chambers nearest to the surface of the body, and we also know by animal experimentation that the current through both arms is quite like the current emanating from these two points in the heart. But the current shown at II (Fig. 3), which passes from the right arm to the left leg, gives the best tracing, as a rule. That is, by referring to the standard of the normal heart, II represents the tracing that is accepted for the normal heart. And it is customary in marking any tracing to indicate on it the course of the current, whether as in I, II, III, etc., up to VI. In Fig. 3 the source of the currents used is shown: for example, in I, it is both hands, in II, right hand

and left foot, in IV, right hand and right foot, and so on. The course of a current is called a "lead."

But of course the strength of the current is modified to some extent by the amount of superlying flesh, and the best records are taken from spare people.

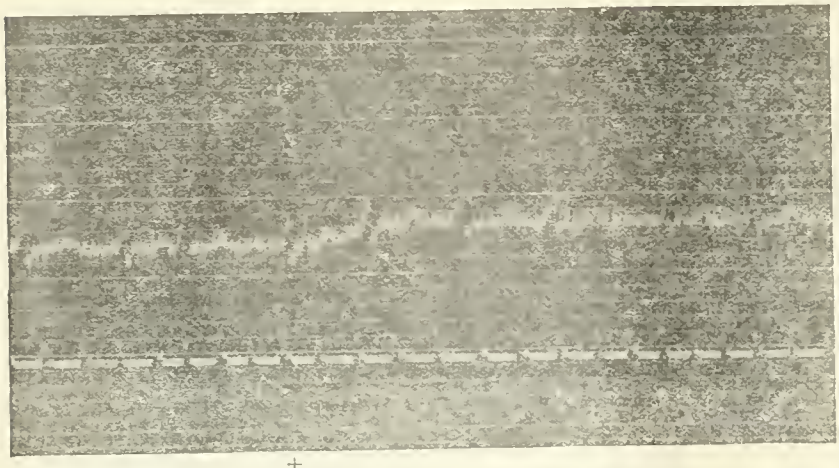

Fig. 7.—Myocardial degeneration. Irregularity in action of ventricles and auricles. Extra ventricular systole (at +). Diminished ventricular contraction. Auricular contraction not always defined.

This apparatus should include a couple of hand, arm or foot baths of metal, zinc being generally used, to which the electric wires are attached, while the hands, arms, or feet are immersed in the salt water of the bath tub. The cost of the whole, as made by Edelmann of Munich, runs from $400 to upward of $1,000, and may be much more, especially if duty is paid on it.

Fig. 4 is a scheme made to represent the electrocardiogram of a healthy adult, and the notches or waves are indicated by letters. It is best to take the tracing when the patient is in the reclining, not the sitting, position. It may be said here that this graphic tracing of the auricular contraction is apt to be better than if taken from the veins of the neck by any other registering apparatus. Moreover, these notches are apt to be well shown in cases of arteriosclerosis and in heart block.

In Fig. 7, at + is seen an extraventricular systole. The diminished contractile force of the ventricles is shown by the comparative shortness of the ventricular notch. The juvenile type of it is also shown by the fact that it invariably drops beneath the level of the other tracings. On the lower line is the record of the time marker. Each abscissa represents one-third of a second. Owing to the fact that the sensitive paper did not move with uniform speed, the time marking is not absolutely though nearly uniform. This is one of the minor errors to which such delicate instruments are liable.

The absence of the auricular notch is apt to be ascribed to some affection around the Keith or Jawara node causing disturbance of transmission.

An effort has been made to construct from a large number of electrograms the tracings of certain well-known forms of valvular disease, such as mitral stenosis, aortic insufficiency, and mitral insufficiency. The difficulty is not so great with mitral stenosis, which in its developed form has characteristic clinical features, and would naturally, at least when there is the "check" that is associated with the presystolic murmur, give a characteristic tracing. But these lesions are so generally intermixed, *i. e.* the valvular lesions are so apt to be multiple, that it must be impossible in the vast majority of cases to dissociate them. Indeed until autopsies have been made in sufficiently large numbers to furnish tracings for individual single lesions we shall not be able to say this or that curve belongs to this or that valve lesion. And inasmuch as this presence of a single lesion is so very infrequent, the call for a special curve tracing to diagnosticate a special valve lesion becomes of less importance from a diagnostic point of view.

It is important to control the electrocardiogram by means of other methods of graphic tracing so that one may help to interpret the other. Kraus and Nicolai believe, however, that the electrocardiogram is even now applicable for clinical medicine, although it must be admitted there is still a lack of correspondence between physiological and clinical tracings. To their minds, however, a diagnosis in heart cases that embraces chemical, microscopic, and bacteriological methods is not complete without this instrument. Briefly, they say (1) that the electrocardiogram depicts the precise nature of the heart's contractions more completely than any other method: (2) that the movements of the auricles are specially well shown; (3) that the time and place of the irregularities are also shown, and (4) that it augments the means of diagnosis and may be used to control other methods.

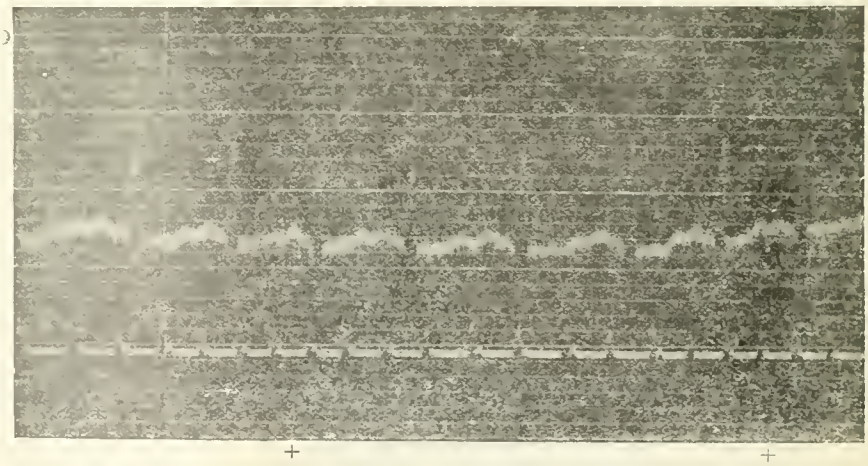

Fig. 8.—Mitral insufficiency. Arrhythmia; irregularity in time and force of ventricular contractions; also in time and force of auricular contractions, but the latter are well marked. At + + are extraauricular systoles.

And yet, according to Pribram of Prague, there is really no standard tracing for healthy adults, though in most instances they tally with Einthoven's curve. Occasionally patients with abnormal conditions of heart and lungs will yield normal tracings.

Sometimes there is a sixth notch. (See Fig. 4.) In children the notches are shorter, and often in persons of powerful build they are higher, but it is not always so. In the pulsus irregularis perpetuus the auricular notch is absent.

According to my notions this method is not, as yet, taking it all in all, so valuable for diagnosis as the polygraphic is or blood pressure or .r-ray work; it is rather an accessory to other means of diagnosis. Though my personal experience with it has been limited, I have seen enough of it to convince me that it has not yet reached the stage where it is worth while for the ordinary practitioner to depend on it in clinical work. Moreover, it is very complicated, consisting of a number of separate apparatuses, requiring much skill to operate. It is also costly and is very easily put out of condition.

From what has been stated it is apparent that the sensational statements which have appeared in the public journals as to the utility of the instrument must be received with much caution. The electrocardiogram does not as yet of itself distinguish uniformly functional from organic heart diseases. Neither can the use of the instrument dispense with the personal examination of the patient. Hence, a

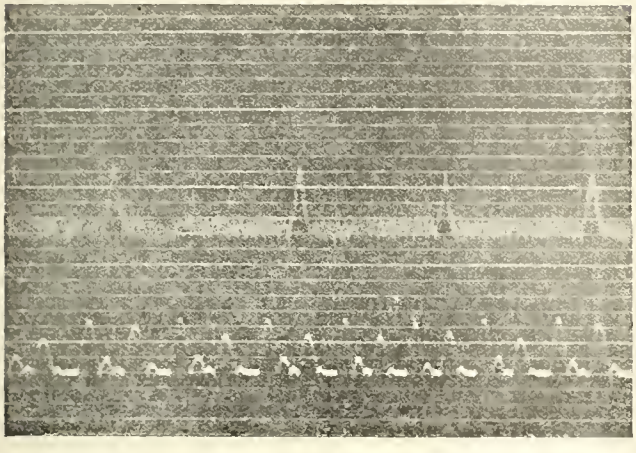

Fig. 9.—General arteriosclerosis with anginal attacks. Showing negative phase following initial ventricular contraction in place of positive phase (inverse type). This is regarded by Kraus and Nicolai as an important sign of beginning arteriosclerosis, and is apt to be associated with cardiac insufficiency. (Franzensbad, July 20, 1910.)

complete diagnosis can not be made by the instrument when the patient and the physician are far apart. Neither the electrographic machine nor any other instrument of so-called precision tells an invariably truthful story. Mechanical difficulties will at times occur, making the picture untruthful. Moreover, as already said, the standard normal curve has not been agreed upon. Strictly speaking, Einthoven has not inaugurated a new method; he has utilized the photographic method of Marey, and the string galvanometer of Ader, while the credit of the completed instrument is due to Edelmann. Einthoven has, however, given close study to the method with the perfected instrument, and he is, therefore, entitled, more than any other man, to have electrocardiography associated with his name.

This much may be truthfully said: The instrument is capable of showing the time and force of action of ventricles and auricles; notes lack of transmission; and demonstrates ventricular and auricular extra-systoles more clearly than any other method. It is certainly useful in various forms of arrythmias, particularly when there is more or less complete auriculo-ventricular dissociation. Electrocardiography has already broadened the knowledge obtained by other graphic methods. But at present the initial cost of the Einthoven machine, and the expense connected with operating and maintaining it, will be a bar to its general use, except in the larger hospitals or research laboratories.

THE USE OF ELECTRICITY IN CHRONIC DISORDERS OF THE STOMACH.

WITH A REPORT OF SIX SELECTED CASES.

By JONATHAN GODFREY WELLS, M.D.,
NEW YORK,
INSTRUCTOR OF DISEASES OF THE STOMACH AT THE NEW YORK POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL,
AND
LOUIS HENRY LEVY, Ph.B., M.S.,
NEW HAVEN, CONN.

Electricity in the treatment of stomach disorders has not been used as extensively as the large percentage of cures due to its use would warrant. This is undoubtedly due to the skepticism of a large number of men as to the value of electricity not only in diseases of the stomach but also in other diseases. With the exception of those writers who have used electricity in stomach diseases, there are some whose books on stomach conditions entirely ignore the electrical treatment. This is surprising, especially since such very good results have been obtained in the past few years by the use of electricity. Those who have treated stomach diseases electrically to any extent are firm believers in its efficiency in certain conditions which have been treated but not alleviated by the regulation medicinal treatment. The only disagreement that exists among those men concerns the particular method to be used. Each man advocates some method of application, but all unite in agreement as to the efficiency of electricity.

That electricity is of decided benefit in stomach diseases has been determined, not only clinically, but also experimentally. The first important thing noticed when electricity was first applied to the region of the stomach was the stimulation of gastric secretion. Among the first observers of this were Bocci,[1] Rossi,[2] Ludwig and Weber,[3] and von Ziemssen.[4] Von Ziemssen experimented on dogs and showed that if the faradic current was sent through the walls of the stomach there was an increase in the secretion of gastric juice. Hoffman,[5] experimenting on human subjects, showed that the secretory functions were influenced by the galvanic current, and that if this current were applied to the gastric region for twenty minutes, an abundant secretion of gastric juice was produced. He thought that the gastric branches of the vagi were stimulated either directly or indirectly. Jones,[6] found large amounts of free hydrochloric acid in the washings of the stomach after treatment with electricity. Before the treatment, tests had shown the absence of free hydrochloric acid. He finds that direct electrization does not always cause secretion of gastric juice. The constant current, however, has done so in many cases. He believes that this is due to a disturbed or deficient innervation which reacts quickly to the faradic current and causes a restoration of normal size and

tone. In summarizing this paper he states that the secretion of the gastric juice is excited by direct electrization in healthy and in many diseased conditions, and that sometimes in clinical work electricity fails to excite the secretion of hydrochloric acid. Beyard and Loye[7] experimentally succeeded in causing the secretion of gastric juice by simple stimulation of the vagi, forty-five minutes after the death of a criminal. Likewise, Pawlow and Schlomowa,[8] experimenting on dogs, showed that the vagi were concerned in the secretion of gastric juice. Goldschmidt[9] is the only worker who failed to induce gastric secretion by either galvanism or faradism. With this one exception, it will be seen from the above that there is produced an increased secretion of gastric juice. The increase of hydrochloric acid, however, is only temporary. That this increased secretion may not be true gastric juice is stated by Freund,[10] who, after a series of observations, concludes that it is a more or less specific mucous secretion. This point should be further investigated. Most of the experiments recorded in literature were carried out on the healthy normal stomach. There are very few conditions of the stomach in which the glandular portion is destroyed to any great extent. In these conditions the healthy glands can always be stimulated by electricity to increased activity, and in this way cause a compensation for those glands which have become impaired and unable to carry on their functions. It is also quite probable that here, too, as in other conditions, an increased demand on an organ will cause an increase in that part of the organ which is called upon to do the added amount of work. In this way new glands are probably formed, with the result that the stomach is ultimately almost restored to its normal glandular activity.

As to the exact effect of electricity on the musculature, considerable doubt exists. This is of importance in those conditions in which the muscular tone of the stomach is affected. The observations made in this connection have also been clinical and experimental. From clinical data, Ewald and Einhorn[11] were able to show that there was an acceleration of the motor faculty of the stomach when treated by percutaneous faradization. They used the salol test and found that the salol appeared in the urine fifteen minutes earlier than usual. Other workers have observed increased peristalsis through the abdominal walls of their patients. It is quite probable, and this fact has been shown experimentally, that what some observers have thought was due to an action on the stomach was really increased peristalsis of the intestines, due to the action of the electricity on the intestines. Fubuni[12] found by means of a Velli's intestinal fistula that the intestinal peristalsis was increased to a high degree by electricity. Kussmaul,[13] on the other hand, thought that the supposed muscle contraction of the stomach was really due to the contractions of the abdominal muscles. Bocci,[1] however, states that he was able to cause increased contractions of the stomach by means of intragastric faradization. Herschell[14] does not think that the contractions can be caused by either the percutaneous or introgastric methods. He states that there is no doubt that these contractions can be produced by the method which he uses, the triphase method. He used this method in experimenting on both healthy people and those suffering with myasthenia. In the healthy people, he found that the stay of food in the stomach was shortened from fifteen to thirty minutes. In cases of myasthenia he used a water-sugar test, and in one case he found the emptying was reduced from four hours to three hours. In two cases it was reduced from three hours to two hours, and in four cases from four hours to two hours. In one case no effect was obtained. In these cases, also, the action might have been due to increased intestinal peristalsis. Riegel[15] in his book concludes the subject by saying that it is well established that the electric current does affect the motor powers of the stomach, but that this has only been deduced from clinical experiments.

Working on the same subject, but in another way, Stockton[16] found experimentally that, aside from producing prompt pyloric contractions, there was very little motion excited in the stomach walls of dogs even when very powerful currents were used. Meltzer[17] passed very strong induced currents through the fundus of the stomach after exposing that organ, and he did not notice at any time any contraction of the muscle. The only portion that seemed to contract was the right side. It seemed as if the contractions grew stronger as the electrode approached the pylorus. He did not succeed in causing a contraction of the pylorus by irritating the corresponding part of the mucosa. He also found that if the stomach was exposed and one electrode placed on the abdominal wall or near the stomach and the other applied to the back or introduced into the stomach that a strong current caused a contraction of the abdominal muscles, but not of the muscles of the stomach. Marshall[18] likewise, working with cats, rabbits, and white rats, and placing the electrodes on different parts outside or inside of the exposed stomach, could not produce any contraction of the muscles of the stomach. With metal instead of sponge electrodes, he was able to produce a slight contraction of the pyloric end. He was also able to produce a prompt contraction of the intestines. Application of electricity to the cut end of the pneumogastric nerve also failed to produce any contractions of the muscles of the stomach. This last finding is somewhat in contradiction to the findings of Courtade and Cyon.[19] These workers found that stimulation of the intact pneumogastric nerve, or its peripheral end, if divided, caused a contraction of the longitudinal fibers, then of the circular fibers. This, however, was immediately followed by a relaxation of the longitudinal, then of the circular fibers and later a period of rest. They also found that there might be a relaxation of the circular fibers at the cardia and pylorus simultaneously with the contraction of the longitudinal fibers. These contractions are abrupt and of such short duration that it is quite probable that they might have escaped the observation of other experimenters. It will be seen that some change does take place in the musculature of the stomach walls. What this change is, is still a matter of dispute. The question is very well summed up by McKaskey,[20] who states that there is not a direct indication or palpable contraction of the stomach as an immediate response to faradic current. It seems to him fairly well established that, independently of such visible contractions, and also in tissues where such contractions could not take place, there are catabolic influences and changes of some sort, the occurrence of which means a betterment in local conditions.

As an analgesic, the results are immediate. The patient gradually feels the disappearance of the

pains after a few minutes' treatment. Riegel[15] recommends galvanic currents in attacks of pain and in other symptoms of irritation following, for instance, adhesive perigastritis and similar conditions. Herschell[21] found that electricity would promptly cure certain forms of gastralgia and epigastralgias. Kemp[22] found galvanism useful in gastralgias, especially those of nervous origin. Reed[23] and Lyon[24] also recommend galvanism for controlling pain. Marshall[25] states that the galvanic current is best in nervous conditions when a sedative is required, especially in gastralgia. In one of our cases which, on autopsy, proved to be a cancer of the liver, pain referred to the stomach was almost instantly relieved by galvanism.

Several methods for applying electricity have been used, and a description of these will be of interest. The relative merits of each method depends on the results obtained, the one most easily applied, and the one which is best borne by the patient. The first method to be used to any extent was that known as the central method. This was used with very good results by Beard and Rockwell[26] in dyspepsias of nervous origin. This method consisted of one electrode in the shape of a cap which was placed on the head of the patient and another electrode was placed on the abdomen. The central method was succeeded by the percutaneous method, and this is still used by some operators. This consists of the application of a large sponge electrode to the back and a smaller one, which can be moved about, to the abdomen. Oka and Harada[27] give thirteen cases treated by this method. Of these, three were cases of chronic gastritis with slight atony, two were chronic ulcers with partial dilatation, four were chronic constitutional conditions with atonic stomach, and four were cases of neurasthenia with dilated stomachs. Five of these cases were completely cured, six were improved, and in only two was there no change. Leube,[28] Bocci,[1] and Rossi[2] also obtained good results. Others who have used the percutaneous method successfully are Hoffman,[5] Kussmaul,[13] McKaskey,[20] Manglesdorf,[29] Jeuttner,[30] Kemp,[22] Lyon,[24] and Rubinovici.[31] This last worker particularly favors this method over the direct method. He says that all writers are of accord in the treatment by direct faradization. It gives very good results, but is inconvenient. He obtained excellent results with the percutaneous method, but found the intragastric method insufficient in some cases. Kemp advises its use in cases where the intragastric method caused discomfort in any form to the patient.

The intragastric method, however, is the one used to the greatest extent, particularly in Germany and America. Direct electrization was first suggested by Canstatt,[32] and his suggestion was put to practical use by Duchenne.[33] Kussmaul[13] treated several conditions by means of this direct electrization. His method consists of placing an electrode contained within a stomach tube into the stomach and the other on the abdomen. He used it successfully in cases of dilatation and atony of the stomach. Bocci[1] used the direct method that is described by Kussmaul. Bardet[34] was the first to suggest the filling of the stomach with water. In this way the electricity would reach every part of the stomach where, by the direct method of Kussmaul, only that part of the stomach which is in direct contact with the electrode was stimulated. Since then this has been the intragastric method most extensively employed.

There are many forms of intragastric electrodes which have been and which are still used. Conforming to the old form of electrode, in which a stiff, thick rubber tubing is used, are those of Bardet, Boas, Stockton, and others. Einhorn[35] made an improvement on these by using a thin flexible rubber tubing with a fenestrated oval shaped hard rubber capsule, in which is contained the end of the metal electrode. This capsule has to be swallowed by the patient, and it is on account of this difficulty that many modifications of Einhorn's electrode have been devised. Some of these modifications consist of stiffer rubber tubing, changes in the shape and size of the capsule, and very recently Bassler[36] has devised a combination electrode and introducer. The introducer pushes the electrode and is removed after the electrode is in the stomach. Other modifications are those of Ewald, Marshall, Lockwood, Reed,[23] and Roberts.[37] Weigel[38] uses a spiral electrode, and Turek's gyromele[39] has also been suggested. In the intragastric method, the patient first swallows some water and then the electrode is placed far back into the pharynx, and is either pushed or swallowed. In the case of the Einhorn electrode, the patient is given some water to swallow while the electrode is being swallowed. In some cases it has been found very difficult for the patient to swallow the electrode, and it has often been coughed up. As a result, much has been lost, and the patient is often discouraged. The stiffer, narrow electrodes, such as Lockwood's, are easier to pass, especially by those not used to the mechanical treatment of stomachs. No instrument, however, is as comfortable to the patient, after it is once down, as the soft, flexible electrode of Einhorn. In removing the electrode, resistance is encountered at the entrance of the esophagus, but this is overcome by the patient swallowing, which causes the larynx to rise and the electrode is easily withdrawn.

Very good results have been accomplished by means of the intragastric method. Leube[28] used it successfully. Stockton[40] treated four cases in which all the symptoms disappeared. Of these cases one was a regurgitation, two were gastralgias, and one was a hyperchlorhydria. Ewald cured two cases of hysterical eructation. Stewart[41] cured one case of chronic gastritis, and in two cases of hypochlorhydria caused an improvement with the appearance of hydrochloric acid. Menzell[42] by means of the direct faradic current, cured three cases of chronic gastritis. Brock,[43] in thirteen cases of chronic stomach disorders, cured two cases, produced an improvement in seven, and in six there was no change. Einhorn,[44] who has probably done more with the intragastric method than any other worker, gives a very interesting table of 177 cases. He divides these cases into three classes, arranged according to the form of electricity given. In the first class there are 118 cases treated by direct faradization. Of these, 72 were cured, 32 greatly ameliorated, 5 slightly improved, and only in two was the condition unchanged. The second class consisted of 21 cases, and comprised that group in which faradism was used after galvanism. Of these cases, 14 were cured, 6 greatly improved, and 1 unchanged. The third class of 38 cases were those treated by galvanism. 27 were cured, 6 greatly improved, 4 slightly improved, and 1 unchanged. The cases consisted of dilatation, atony, hyperchlorhydria, enteroptosis and hyperchlorhydria, enteroptosis and atony, gastric neurasthenia, chronic gastritis, rumin-

ation, gastralgia, erosion of the stomach, duodenal ulcer, and gastrosucchorea. Reed[23] has used this method to good advantage in cases of muscular atony, in atonic dilatation, regurgitation, rumination, nervous dyspepsia, and chronic gastritis. He does not favor its employment in hyperchlorhydria. Kemp[22] recommends it in chronic gastritis, atonic ectasia, atony, diminished secretion, gastralgias, nervous anorexias and hyperacidity.

Another method more recently used is the treatment by static electricity. This also has its followers, and as their results have been very favorable, they recommend this process. Setters[45] found in the treatment of ulceration of the stomach that static electricity gave him decided and very gratifying results, and that during the treatment there was an improvement in nutrition, tonicity, and secretion, which had been normally deficient. Bond,[46] writing of atony, stated that nothing but electricity has ever been able to decrease the size of the atonic stomach, and that most good has been done by the current from the static machine. He has treated 35 cases of stomach disorders by this method, and the results were very gratifying. Tousey[47] states that motor functions are also favorably influenced by the static indirect current, and that strong visible contractions occur.

The polyphase or triphase method is the one recommended by Herschell.[48] He describes the apparatus devised and used by him in his book. This form of electricity may be applied either percutaneously, in which two electrodes are placed on the back and one on the abdomen, or it may be applied intragastrically, in which the abdominal electrode is replaced by an intragastric electrode. In one paper he describes 48 cases, 31 cases of which were cured, 10 improved, and 7 showed no beneficial results. He treated cases of chronic gastritis, neurasthenia, gastroptosis, atony, and atrophy of the mucosa. He believes the triphase alternating current to be the very best method for restoring tone to the musculature substance of the gastrointestinal tract, and that it has the advantage that it is not necessary to introduce electrodes into the stomach in most cases. Reed[23] states that the polyphase current raises the blood pressure in numerous cases of neurasthenia, and that it is useful in nervous dyspepsia, hyperesthesias of gastric mucous membrane and muscular atony of the stomach.

Treatment by high frequency currents is another method which is used, and this method so far has been used in the hands of a very few workers in England and in France. Its action is similar to that of the static current, but there is less sensation. It is used mostly for atonic dyspepsia, gastric dilatation and hyperchlorhydria. Tousey[47] gives one case of atony of the stomach which was promptly and favorably influenced by high frequency currents.

As a therapeutic agent, electricity would be indicated in any of the chronic stomach disorders. The use of the proper form of electricity is an essential factor for the successful treatment. A general statement may be made by saying that in those conditions where there is a disturbance of the secretory function of the stomach, galvanism will restore the secretion sooner than faradism. In disturbed motor conditions, faradism has been successfully used in a large number of cases, whereas in functional conditions in which pain is present, galvanism is better than faradism. In some conditions application of both forms of electricity is necessary, but most cases will respond to a general electrical treatment.

The frequency and length of each treatment depends considerably on the conditions to be dealt with. The different writers are not all in accord as to the frequency and length of each treatment. Some suggest daily treatments and others every second day. Some suggest eight and ten minute treatments, while others suggest as much as fifteen and twenty minutes. In our work we applied electricity twice a week, each treatment lasting ten minutes. The treatment in the beginning may be given oftener, either daily or every other day, and this may be changed later to two treatments each week. In the different cases treated by the various workers the condition had persisted from six months to twenty years before the application of electricity. The ages of the patients ranged from nineteen years of age to seventy years. The strength of the current is to be determined by the patient himself. No set amount should be decided upon beforehand. The strength to be used is that which is most comfortably borne by the patient. During the period of each treatment, the strength may be increased gradually as the patient becomes accustomed to the sensation.

In the following cases electrical treatment was used to good advantage. The method employed was the intragastric method, and Einhorn's electrode was used with the negative electrode in the stomach. The treatments were given twice a week for periods of ten minutes each.

Case 1: *Chronic Gastritis.*—J. K., age 40, piano packer, German. The patient had been a very heavy beer drinker up to nine years ago, when he had his first attack, similar to the present attack. During the past nine years he has had many attacks. The present attack had a duration of four weeks. It consisted of pains which were sharp and at times long continued. The pain was localized in two or three spots. It was independent of the kind of food eaten and also of the time of eating. During the four weeks the patient had vomited three times. The vomitus was mucous, with a bad odor and a sour taste. Pyrosis was present, and there was a sour taste in the mouth in the morning. He had headaches at times. His appetite was poor and his bowels regular. The appearance of the patient was good. He was stout and looked well nourished. His face had a tired expression. The tongue was heavily coated with a greyish coating. Examination of the stomach contents one hour after a test breakfast of two rolls and a glass of tea showed no free hydrochloric acid present. This was a typical case of chronic gastritis, and the patient was placed on the customary medicinal treatment for four weeks without any beneficial results. On this account electrical treatment was suggested. To increase the hydrochloric acid secretion, galvanism was used, and, although as a rule in chronic gastritis there is very little or no loss in motor function, it was deemed advisable to add faradism to the treatment. On application of the electricity the pain gradually disappeared, and even after the first treatment the patient felt greatly relieved. After two weeks of treatment, all of the symptoms disappeared and the patient discontinued treatment. There has been no recurrence of symptoms after two months.

Case 2: *Gastralgia.*—N. L., age 31, cutter, Russian. This patient has had trouble with pains in the stomach and intestines at various times during a period of five years. He now complained of pain

on the left side, which had been present for almost a year, but which had been getting worse. He also had attacks of intestinal pain. The pain radiated toward the left shoulder. The pain was not constant. Sometimes it lasted half an hour and at other times longer. It was independent of the time of eating or of the kind of food eaten. At times there was tenderness over the area of pain. He had no headaches, no dizziness, no vomiting. His appetite was good, his bowels irregular, and he slept poorly. The patient was of a neurotic temperament. He was pale, and his face had an anxious expression. No examination of the stomach contents was made, but from the history of the case and the symptoms the case was evidently one of gastralgia. The case was treated symptomatically with the usual drugs and diet for three weeks without any improvement. Galvano-faradism was applied, and the pain was very much lessened after the first treatment, the patient feeling much better. This treatment was continued for three weeks, and the patient left, saying that he felt as if he had a new stomach. The symptoms had entirely disappeared, and the case was symptomatically cured. The patient continued entirely well for five weeks, when, on account of an indiscretion in diet, the pains returned. The patient was treated electrically again for one week, and after one month the symptoms have not returned. In both of these cases cures were effected. The cures, of course, only pertain to the symptoms. How long these cases will stay cured evidently depends on the care which the patients take of themselves. Some cases have been reported permanently cured after a period of several years.

Case 3: *Ulcer ventriculi, atony, hyperchlorhydria.*—R. H., age 23, clerk, American. For two years this patient complained of the following symptoms, which gradually grew more marked: Weakness, hot flushes, marked nervousness, and eructations of very sour fluids. The eructations were more marked after a fluid meal, but occurred not infrequently when the stomach was empty, as early in the morning. Steady, gnawing pains was experienced in the region of the stomach nearly continuously. This pain was somewhat relieved by the injection of proteids. There was no history of vomiting or hemorrhage from the stomach; bowels normal. General appearance poor, anemic. Weight, 125 pounds. Tongue clear, moist; heart and lungs normal. Right kidney moveable, second degree. Stomach three inches below umbilicus; general tenderness over area of stomach. Analysis after test breakfast showed free acid, 40; total, 60; some blood. The patient was put on appropriate diet for ulcer, with slight improvement for two weeks. The patient went to the country for two weeks and returned because the symptoms suddenly became worse and he vomited blood. Operation was advised, but refused, and the patient underwent a fast cure in a hospital without any permanent results. Returned to clinic about two months later, at which time free acid was 70; total, 100. He was given electrical treatment by means of the Einhorn method for one month, twice a week. The pain was markedly relieved and the lower border of the stomach became elevated to the umbilicus. Analysis showed the free acid to be 24, and the total 60. Patient went to work in the country. Four months later he returned and was operated on and an ulcer found near the pylorus.

Case 4: *Nervous regurgitation.*—I. M., age 36, cutter, Russian. For several years overworked until he became very nervous and run down. He complained chiefly of eructations of food and constipation. He was placed on sedatives and made to eat plenty of food and take plenty of rest in a well ventilated room. At the end of one month he felt well and looked much improved, but still regurgitated as much as ever. Food regurgitated at end of one hour after a test meal showed the stomach contents to be normal. He was given faradism for ten minutes twice a week for two weeks, at which time the regurgitation had entirely stopped. He remained well for four months. Regurgitations again appeared, and the patient was lost sight of.

Case 5: *Severe Gastralgia.*—P. M., age 42, porter, Irish. Patient complained of very severe pain in region of the stomach, which occurred about twice a week and lasted for several hours. These pains annoyed the patient for several years. He was operated on at different times and his appendix removed, his gall-bladder drained, and finally a gastroenterostomy performed. External electrical treatment was tried, and relieved the pain somewhat during two attacks. The internal method gave no results. The patient disappeared and was lost track of. The electricity was tried in this case because every other method of treatment had been employed without results.

Case 6: *Chronic Gastritis.*—P. M., age 48, laborer. The history was that of the ordinary alcoholic with gastritis. Analysis on the second visit showed no acid present in the stomach, but ferments present in small amounts. Electricity was administered internally for a period of six weeks. Analysis after test breakfast showed free acid, 20; total, 40. The patient felt much improved and left the city to go to work.

In conclusion, it is very evident that electricity is beneficial in all chronic conditions of the stomach which have not responded to the regular medicinal treatment and diet, and that on account of the large percentage of cures and improved cases due to its use electricity should be more largely employed than it now is.*

*Since this paper was written we have come into possession of a copy of "Philip's Inquiry," published in 1818, dealing with experiments conducted during 1815 and 1817. Some of these experiments deal with galvanic stimulation of the cut ends of the vagi. Philips claimed that he was the very first man to use galvanism for this purpose. The vagi of two dogs were cut immediately after the dogs had eaten a large meal consisting of mutton. The vagi of one of the dogs were stimulated with the galvanic current, and later both dogs were killed. In the stomach of the dog whose vagi were stimulated the food was half digested and the blood-vessels greatly congested. In the other dog the food had not undergone any change, nor was there any change in the blood-vessels in the stomach. Philips employed galvanism in the treatment of dyspepsia with marked success. His method was a percutaneous one, in which one electrode was placed at the back of the neck and the other to the pit of the stomach.

DIRECT TRANSFUSION.*

By F. D. GRAY, M.D.

SURGEON TO CHRIST AND THE CITY HOSPITALS AND CONSULTING SURGEON TO NORTH HUDSON HOSPITAL.

Technically considered, direct transfusion of blood is one of the minor operations, but as regards its purpose and results it deserves to rank as a major procedure. Even from the standpoint of technique, however, no other minor operation demands the same delicacy of detail and extreme of care.

Blood transfusion, either direct or indirect, is by no means a new proposition. It was known to the ancient Egyptians and is referred to in the works of the Romans. The earliest authentic case is that of Pope Innocent VIII, who was operated on in 1492 by his Jewish physician, whose name has not come down to us. The blood of three boys was passed into his veins, but without marked benefit. The discovery of the circulation by Harvey, in 1616, gave a new impetus to the subject, and research was established on animals. Lower, in 1666, wrote the first detailed account of the method of performing transfusion, and in the same year Jean Denys, in France, carried on similar experiments. He also performed the operation three times successfully on human beings. Following his report transfusion was carried on extensively, sometimes from animal to man and sometimes from man to man, either by direct communication of vessel to vessel, or through the mediation of a quill or cannula of silver or bone, or indirectly by a syringe or pump. Other successes were reported, but the method aroused fierce opposition, and, as a result, in France the procedure was forbidden (1668), except by express permission of the Faculté of Paris. About the year 1800 the operation was revived and given an important position in experimental physiology. Shortly after this it was first noted that the blood of an unlike species was liable to cause disturbing or even fatal symptoms in the person to whom it was transferred. About 1835 Bischoff experimented with defibrinated blood, and its use became an established procedure up to about the middle of the century. In 1863 Blassius collected one hundred and sixteen cases of transfusion performed during forty years, and found that there had been fifty-six successful results. All of these were indirect transfusions, and in two the source of the serum was an animal. Transfusion from animal to man was reintroduced, but after Landois' discovery that the serum of one animal may cause destruction of the red blood corpuscles of another (hemolysis) the use of heterogeneous blood was abandoned. It was found, also, that defibrination of the blood was a source of danger, as it contained a fibrin ferment which might cause intravascular coagulation. These limitations, together with the general introduction of intravenous injection of normal saline solution, about 1875, caused a gradual disuse of transfusion, which lasted until some time in the eighties, when it was taken up with renewed enthusiasm.

Three methods of transfusion have been, first and last, employed, namely, the intravascular, the intraperitoneal, and the subcutaneous. The work of Carrell and Guthrie was the foundation for a great advance in the use of the intravascular method, which is the only one deserving the name of direct transfusion. As a result of their experiments a practical method of end to end suture of vessels was perfected. End-to-end vascular suture, however, is a tedious and delicate procedure, and Crile greatly simplified the technique by the use of a cannula adapted from one that had already been introduced by Quirole and Payr. Modifications of the Crile cannula have also been made by Elsberg and Bernheim.

The great obstacle formerly in the way of transfusion of blood from one individual to another was its coagulability. Blood containing fibrin and corpuscles was almost certain to clot before it could be transmitted by any indirect method, and the same was likely to occur when an attempt at union or inosculation of vessels was made, the clot forming at some point of the vessels where the endothelium was traumatized, or else in the tube of one or an-

* Read at a meeting of the Practitioners' Club of Jersey City, November 8, 1910.

other sort used to effect artificial communication. Carrell demonstrated that by the use of sufficiently minute instruments and sutures, accompanied by special training and practice in working on the delicate structures involved, either end to end, end to side, or lateral anastomosis of like or unlike vessels (arteries or veins) could be accomplished without subsequent leakage or coagulation. This removed the chief impediment to direct transfusion, but left the procedure available, mainly, to those with opportunity to develop technical skill by experimental operation. Here Crile came to the rescue by devising a small cannula, or rather, a series of them, of different caliber, which serve much the same purpose in vaso-anastomosis that the Murphy button does in intestinal anastomosis—viz., a framework over which the junction is effected. The open end of one vessel is drawn through the cannula and rolled back over the outside as a cuff, where it is held in place by a ligature, thus exposing the intima. Over this is slipped the open end of the other vessel and ligated. Thus endothelium is opposed to endothelium, offering a surface on which coagulation will not take place if unnecessary traumatism has been avoided. In this way the tedious and intricate anastomosis of vessels by numerous fine sutures was avoided and the procedure placed within the reach of any one with sufficient skill to dissect up an inch or two of superficial artery and vein and tie a couple of ligatures. Usually the radial artery of the donor and the median cephalic vein of the recipient are used for the anastomosis, about three cm. of each vessel being carefully freed, collateral branches being ligated when necessary. Crile has, however, recently demonstrated that a vein may be successfully used in the donor as well as the donee, there being quite sufficient intravascular pressure in the veins to afford the necessary *vis a tergo*. It would seem to the writer, however, that it would be better, other things being equal, to give the patient arterial than venous blood.

Preparation of the vessels is much facilitated by use of the special tiny hemostats of Crile and the small tenacula of Elsberg. Crile's compression clamps, one arm rubber shod when in use, should be used to control the exposed vein and artery while the ends are being joined, a permanent ligature being applied peripherally on each, and division being made with very sharp scissors just proximally to each ligature. The compression clamps being applied as near as possible to the proximal end of the exposed vessels, a length of about two cm. is thus left free for the necessary manipulations of the anastomosis. A ligature applied proximally around the vessels and twisted in the bite of a hemostat makes an effective substitute in absence of the Crile compression clamps. When the anastomosis is perfected the clamp or twisted ligature, first on the artery and then on the vein, is loosened and the transfusion current is at once established, as may be proved by pulsation and fullness of the recipient's vein. Warm, wet compresses or warm, constant irrigation over the wounds encourage a proper flow of blood.

Elsberg has invented a valuable modification of Crile's cannula by bisecting it longitudinally and attaching each half to the end of a metal arm. The arms are joined so as to be parallel and a screw at the end opposite the cannula operates them much the same as a monkey wrench, approximating and separating them at will. When separated the lumen of the cannula is larger than the largest radial artery, and when closed it is small enough to compress any radial. After the artery is exposed and isolated the cannula, widely open, is slipped under and around the vessel. It is then screwed up until the two halves tightly compress the artery. The latter is then tied off one cm. from the tip of the cannula. Before the artery is divided three small tenacula are attached to as many points on its circumference, just proximal to the ligature. An assistant makes traction on the tenacula while the operator cuts the artery between them and the ligature. The stump of the artery is then pulled back on the cannula as a cuff, where it is held in place, without a ligature, by four small backward projecting points on the outer surface of the cannula blades. There is no bleeding from the artery, the cannula itself acting as a hemostatic clamp. The vein of the recipient is then exposed (but not isolated), two ligatures being passed around it, the peripheral one of which is tied in the usual manner. A transverse slit is then made in the vein, the cannula with the cuffed artery introduced, and the remaining ligature tied around the cannula and vein. The cannula is now screwed open and the blood allowed to flow. The rapidity of current can be regulated by screwing or unscrewing the instrument.

Note the advantages of Elsberg's over the Crile instrument. The latter requires isolation of both vein and artery; the former needs isolation of the artery and simple exposure of the vein, a material saving of time. With Crile's instrument the end of one vessel must be threaded through, which is not always easy, while the Elsberg is simply clamped around the vessel before it is divided. Then, again, in order to suit the various sizes one must have and select from a full set of Crile cannulæ, but with the Elsberg one instrument serves the whole purpose. Also the cuffing of the vessel over Elsberg's is easily accomplished without preliminary stripping of adventitia and consequent traumatism of the vessel walls which is necessary in using the Crile. Finally the Elsberg instrument may be made accurately to regulate the blood flow by separation or approximation of the blades.

Both of the cannulæ described effect *direct* anastomosis of the vessels, which in regard to prevention of clot formation is ideal, but it has the disadvantage of requiring the isolation of a considerable length of artery and vein or else putting a troublesome strain upon them after they are united. In other words, it is difficult to keep the arms of donor and recipient in sufficiently close apposition to prevent undue tension, which interferes materially with the blood current and may even stop it. A latitude of an inch or two in this respect means a large element of freedom to the operator and comfort to both donor and donee, as well as, sometimes, the actual success of the operation.

Brewer has devised an ingenious set of glass tubes which serve as connecting links between the vessels and obviates the difficulty mentioned. Brewer's tubes are about two inches in length, with a slight bulbous tip at each end, the smaller to be inserted into the artery of the donor and the larger into the vein of the recipient. They are made in three or four calibers and are straight, curved, and angulated to suit different positions. The coupling is made with ease, and no strain is placed on the vessels. The only objection to Brewer's tubes is the possibility of coagulation in the lumen. This

would always occur on the surface of naked glass, but Brewer prevents it by coating the interior with sterile, liquid paraffin. I have learned by practical experience that merely dipping the tube in melted paraffin will not insure thorough coating of the lumen. It is necessary to allow the tube to remain immersed until all minute air bubbles cease to rise. One then knows that the tube is completely filled just as the cessation of air bubbles from an immersed plaster of paris bandage shows that it is saturated. Then a quick, sharp shake, as one shakes down the mercury in a clinical thermometer, dislodges the excess paraffin and the tube is thoroughly coated inside. For the general practitioner who has not considerable experience in vasorepair, the Brewer tubes are no doubt the simplest and most satisfactory device for coupling the vessels.

One might add that on its face Hartwell's proposition to unite the vessels by inserting the divided end of donor's artery into a slit in, or the open end of, the recipient's vein and making the vein fit the artery by closing any space about the latter with an artery clamp, reduces the problem to its simplest terms. It seems a question, though, how secure such an anastomosis would be.

Among the details of technic in the operation of transfusion it may be mentioned that the donor and donee should be placed on parallel tables, head to foot, with their respective left or right arms, as it may be, in contact. A wide double bed, in an emergency, where tables are not available, may answer. It is desirable, also, to have the donor on a table where Trendelenberg position may be secured, with head low, in case of threatened syncope. There is no arbitrary time limit in this procedure; neither can the actual amount of blood transfused be estimated. All statements that a certain number of ounces were donated are, of course, imaginary, as there is absolutely no means of knowing. The operator, or an associate, must carefully watch the condition of both donor and recipient (especially the latter) throughout for any evidence of syncope in the one or overdistended vascular system in the other. Acute cardiac dilatation, with its consequent pulmonary congestion in the recipient, is the only serious immediate danger in the process. For this reason an accurate outline of heart dullness should be marked on the surface in advance, and this should be frequently checked up by percussion. Any material increase in cardiac dullness or sudden development of dyspnea calls for cessation, or at least interruption of the transfusion with employment of remedies. Whenever the circumstances of the case will permit a preliminary test to determine the affinity, or otherwise, of donor and recipient's blood should be made to avoid possible hemolysis, which sometimes causes serious anemia, and has resulted fatally. When the blood of donor and recipient proves incompatible a new donor should be secured. Naturally, some cases requiring transfusion are so urgent that preliminary blood tests are impracticable. The test is based on the assumption that a donor's serum that causes agglutination in the blood of recipient is liable to produce hemolysis, and therefore is unsuitable.

Securing a donor is perhaps the most frequent obstacle to the performance of transfusion. Not even members of the patient's family are always willing to submit to what they fear is a painful and possibly dangerous procedure. I have found this true in one of my cases. On the other hand, I had a generous offer in another case from a nurse in the training school who was an entire stranger to the patient, and in still another a patient in an adjoining ward bed, in good health but for a fractured leg, donated the blood. On the whole, I believe that in most cases a donor may be found. The actual pain of the operation is but slight under local anesthesia, 0.1 per cent. cocaine solution, with adrenalin, being used. General anesthesia is inadvisable because the recipient is usually in a poor condition for ether or chloroform, and the donor's blood becomes more or less carbonized; yet general anesthesia of the donor is permissible when consent cannot otherwise be obtained.

The most brilliant results of transfusion have naturally been obtained in cases of profuse hemorrhage, especially of the traumatic or some other accidental form. Where the problem is simply to replace, in whole or in part, loss of normal blood, transfusion fulfills all the indications; even when hemorrhage is due to a blood dyserasia or defect in the vessel walls, as in purpura or hemophilia, the results have often been very satisfactory. Another promising class of cases are those requiring operation, but unfit for the same on account of simple anemia or general debility from suppuration or other exhausting discharges. Transfusion will restore a sufficient resistance in these individuals to make major operations quite feasible. It would seem that where a suitable donor is available loss of life from shock, traumatic hemorrhage, hemoptysis, hematemesis, hematuria, hemorrhagic typhoid, ruptured ectopic gestation, or postpartum hemorrhage is quite unnecessary. Illuminating gas poisoning is also greatly benefited. The procedure is so simple and the result so prompt that the remedy should always be borne in mind and arrangements made to institute this life-saving operation without loss of time.

An alluring field of possibility has recently been opened by the suggestion that cases of spontaneously cured carcinoma, of which some undoubted instances exist, develop an autoantitoxin and that transfusion from such subjects makes probable a cure in many inoperable cases of cancer. Not sufficient clinical experience has been adduced to prove the truth or error of this hypothesis, but it offers a fruitful field of research. Much has been hoped from transfusion in pernicious anemia, leukemia, and allied disorders where a profound blood disorder exists, but as far as clinical experience has proved, up to date, those expectations have been without foundation.

In conclusion let me append a brief report of three cases in which I have used direct transfusion within the past year:

Case I.—A boy of eleven, hemophiliac, as shown by obstinate bleeding after extraction at different times, of unsound teeth, this being, apparently, the only traumatism he had suffered. He was admitted to my service at Christ Hospital, in December, 1909, several days after a tooth extraction, from which he had persistently bled. He was profoundly anemic. All remedial measures, such as packing the tooth cavity, styptics, adrenalin, etc., failed to control the hemorrhage, and his condition became desperate. He was waxy, almost pulseless, extremities edematous, and all indications pointed to a fatal issue. Transfusion being decided on, and the various members of his family refusing to act as donors, I tried to secure one from a Mills hotel, in New York, for pay. One promised to come but failed to appear. A nurse in the hospital very nobly offered her serv-

ices, but was prevented by order of the superintendent, as her parents lived at a distance and could not be consulted. The ambulance driver, a healthy young man, then agreed to donate the blood for a financial consideration. The operation was done with local cocaine anesthesia on both donor and donee, and was practically painless. Brewer tubes were used. Upon connecting the vessels pulsation was immediately apparent in the vein of the patient, but after seven minutes it ceased, owing to a coagulum in the tube. While unsatisfactory, on this account, the transfusion supplied the boy with enough new blood to establish hemogensis, and he made a gradual and complete recovery. Within three minutes of the beginning of blood flow the patient became slightly dyspneic, but this very soon disappeared; no doubt, there was slight cardiac dilatation and pulmonary congestion. Twelve hours after the operation there was an attack of hematuria, which, however, did not recur; this was probably the result of a mild hemolysis.

Case II.—A girl of thirteen years, admitted to North Hudson Hospital, suffering from menorrhagia. It was her first menstruation, but she had been purpuric for some time, as evidenced by ecchymosis on various parts of her body. Her condition on admission was practically that of a woman with severe postpartum hemorrhage. Packing the uterus, as well as possible in a girl of that age, was unavailing, and after twelve hours in the hospital I prevailed on her mother, a robust woman, to donate blood for transfusion. At the time of operation the patient was *in extremis*, markedly exsanguinated, pulseless at the wrist, and had a marked degree of air hunger. In fact, I was very fearful of a fatal result before I could accomplish the anastomosis. Nothing of interest occurred in the technic of the case, except that I profited by my experience in Case I, and secured a perfect coating of the lumen of the Brewer tube and was troubled by no coagulum. The satisfaction of seeing a patient brought back from the very verge of dissolution by such a simple expedient is inexpressible. One has the not very ordinary conviction of having actually saved a life that, otherwise, would have been lost. In this case the pulse came down within twenty minutes to 120, and was of a good quality; the face regained color and the air hunger disappeared; in fact, a dying condition was transformed into a quite normal one. The effect of a twenty-minute blood loss on the mother was practically nil. The patient made a rapid and complete recovery, and there was no return of purpura.

Case III.—A man, aged forty, suffering from a self-inflicted stab wound in the left fifth intercostal space in the mammary line, was admitted to my service in the City Hospital with all the evidence of serious hemorrhage. Pulse was 180, and almost imperceptible, the patient being only semiconscious. His condition contraindicated giving a general anesthetic for the purpose of determining the source of hemorrhage, and as a temporary expedient transfusion was determined on, a patient in the same ward generously donating the blood. A Brewer's tube was used with perfect satisfaction, and a twenty-five minute transfusion was given, the pulse rate coming down to 130, and the patient regaining full consciousness. The pulse subsequently dropped to 118, and remained of good quality for nearly twenty-four hours, the condition being so gratifying that I deferred searching for any source of internal hemorrhage. At the end of twenty-four hours the pulse and temperature rose suddenly and the patient died within an hour, and before I could be summoned. No autopsy was permitted and I am uncertain whether death was due to a renewal of hemorrhage or to hemolysis.

As a last word I would urge the more frequent resort to this life-saving little operation which in its present state of development is easily within the reach of any physician.

62 Madison Avenue.

ON PERCUSSION AND ON PERCUSSION OF THE KIDNEYS.

By OTTO LERCH, A.M., M.D., Ph.D.,

NEW ORLEANS.

PROFESSOR OF MEDICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC.

Topographic percussion means the determination of the boundaries of the organs of the body by means of percussion and the projection of these boundaries upon the body surface. The various methods now employed yield good results in the hands of skilled observers, yet two observers comparing their results will often differ as to the exact location of these boundary lines. Such a difference depends partly on the acuteness of the sense of hearing, and especially so on the strength of the percussion stroke.

Whether we employ superficial percussion in order to determine the lines of organs or parts of organs that lie next to the body wall, or deep percussion to map out organs that are deeply located, the difficulty of obtaining uniform results remains the same. The percussion stroke depends entirely on the judgment of the examiner, and one man will consider a stroke light when another will consider it far too strong. Whether superficial or deep percussion is used, a light and delicate stroke, differing only in a slight degree of strength, must be used in order to obtain trustworthy results. This seems to be especially difficult for most practitioners, and we find often widely varying results of percussion by different examiners. Palpating percussion and auscultatory percussion have been introduced to improve on the old method without overcoming the difficulty.

In order to eliminate the most important factor of the two—the percussion stroke—I have used for years and have taught in my lectures the *drop* instead of the *stroke*. I find that the plexor-plexímeter percussion is easiest to learn and gives the best and most uniform results by this method. As plexímeter, I use a thin ivory plate, and as plexor a hammer with a black rubber or ebony handle and heavy steel head with black rubber tip.

The hammer is very lightly grasped at the end of the handle between the thumb and index finger, the end of the handle resting on the third finger and the palm of the hand. The plexímeter is placed upon the portion of the body to be percussed, with a slight movement of the wrist the hammer is lightly tossed up and the hammer head is allowed to drop upon the plexímeter with its own weight. As soon as the border of a solid organ or the boundary between two hollow organs is reached, the rebound of the hammer will be more or less, according to the amount of air beneath; practically no rebound is noticed if a solid organ is next to the surface. At the same time the slightest change of vibrations is felt in the finger tips that but lightly hold the hammer, as well as in the hand, and a decided change in the note is

readily perceived. We have, then, at once three criteria by which to judge whether the border of an organ is reached.

This method excludes to a very large extent the individual feature of the usually practised percussion and makes the results more uniform.

Fig. 1.—Cirrhotic Kidney.

The results that apply to superficial and deep percussion in the usual way: Application of plexímeter and strength of stroke, the placing of the plexímeter without pressure, a delicate stroke for light percussion, a slight pressure of plexímeter and a stronger stroke for deep percussion, apply to this method. We simply replace the stroke by the drop. Of course it must be left to the examiner how much the drop must be, still it is easier to judge on account of the three criteria we have the rebound of the hammer seen, the change of vibrations felt, and the changing sound heard. It happens almost daily in my clinical lectures that I am told that I change the strength of the stroke on reaching the border of an organ, the student observing the rebound of the hammer lessening on reaching a solid organ.

Finger-finger and finger-plexímeter percussion may be used, but this requires more skill, as it demands a perfect relaxation of the wrist. With my method I have obtained accurate results, lines corresponding to the large vessels in the chest above the heart, the deep dullness of the heart and liver, the dullness of the spleen, lesions in the lungs, and abdomen. The stomach can be differentiated in most cases from the colon. Results many times tested and found correct on the cadaver.

Percussion of the Kidneys.—If we look over the textbooks on diagnosis we find a unanimous opinion that the percussion of the kidneys is practically valueless. Sahli is emphatic on this subject. In his classical work, "A Treatise on Diagnostic Methods of Examination," under the title of "Topographic Percussion of the Kidneys," he says: "The anatomical position of the kidneys shows how impossible it is to limit their boundaries by percussion. Their deep position prevents percussion from in front, and the thick layers of muscles behind produce a dullness which such a structure as a kidney could not produce. If we percuss a patient whose kidney has been removed we can demonstrate the same vertical line of dullness as in a patient with an intact kidney. It corresponds to the outer edge of the sacrospinal muscles and has nothing to do with the kidney."

Da Costa, in his book, "Principles and Practice of Physical Diagnosis": "In attempting percussion of the kidneys the diagonal decubitus is perhaps the most satisfactory posture for the patient to assume, in order to relax the tense lumbar muscles, but even in this position it is impossible to reach the normal kidneys by percussion, owing to their deep situation. The chief value of percussion of the kidneys relates to determining the presence or absence of colon tympany over a mass below the left costal arch, which may be a tumor either of the kidney or of the spleen. Posteriorly renal dullness is inseparable from that of the overlying lumbar muscles, the intervening spinal column, and the adjacent spleen and liver."

It is useless to quote any further; this is the consensus of opinion.

Some writers have nothing to say on this subject at all. I have never seen kidney percussion taught. I will, however, mention that Prof. Dr. E. Grawitz of Berlin told me that the late Prof. Gerhardt had expressed the opinion that the kidneys could be percussed and requested him to study the subject. Other work, however, prevented him from following the suggestion. With my method I have percussed the kidneys for years, and have kept record since 1908, now having several hundred cases tabulated. I find that these organs can be mapped out with accuracy and ease, showing changes in size of a small fraction of one centimeter.

The percussion is best performed with the patient lying face downward with a cushion under his belly, in order to put the muscles of the back on tension. This muscular stretching is not necessary

Fig. 2.—Congested Kidneys in a Case of Dilatation of the Heart.

if disagreeable to the patient. It is immaterial whether the colon is filled with fecal matter or distended with gas, and it is unnecessary to empty the intestines before proceeding to percuss. This method gives good results with infants and adults, young or old, fat or emaciated, and it matters not

whether the abdominal cavity is filled with serum or pus.

That actually kidney dullness is heard, and that these organs are projected upon the back, that we are not deceived by muscular dullness or fecal matter contained in the colon is shown by the location of the percussion dullness, the left a little higher than the right, exactly corresponding to the location of the kidneys in the body. The form of the percussion dullness corresponds to the form of the kidneys, one checking of the other, the right, the left, the lower border, the upper, the outer, the inner lateral border; even the hilum can be mapped out without any difficulty, and as the location of the left kidney is a little higher than the right kidney, these checks become of still greater value.

In cases of movable kidney with palpable organ the check is perfect. We find on percussion the palpated organ displaced. Occasionally it will float back into proper position when the patient assumes the posture necessary for percussion. However, if we repeat the process we will discover this without trouble. Usually the kidneys will at least partly return to their natural position—that is, a kidney that can be palpated full length in the abdomen will very frequently be found only one-third or one-half of its size downwardly displaced (percussion

Fig. 3.—Right Nephroptosis.

dullness). If the kidneys have turned under an angle it may appear smaller in size, and especially so when completely turned and held imbedded by the intestines. Rolling the patient in a horizontal position around, himself displaces the kidney; making him jump from a chair replaces it. This may prove a valuable therapeutic measure in Dietch crises. Nothing more need be said as to the method, except that caution has to be used when, percussing downward, striking the diaphragm a dull note is heard. The percussion must be continued downward and will clear up again when the kidney is displaced. Liver dullness and splenic dullness do not interfere. Very light kidney percussion gives the projection about half size, a superficial dullness of little value for practical purposes except as control.

In every case the clinical symptoms correspond to the percussion figures. If these indicate a contracted condition of the organ, more or less advanced, one or both of the kidneys will be found decreased in size. If a diagnosis of congestion of the organ or of the large white cirrhotic kidney is made the percussion figure will bear out the diagnosis. In movable kidney we find the expected downward displacement of the projected figure.

The reproduction of photographs of a few cases taken from my records will illustrate the subject.

The size of percussion figure corresponds to the actual size of kidneys, and is usually 10 x 4 cm. Any increase or decrease, except in very large or small persons, means a pathological change.

At the beginning of the summer I commenced testing my method on the cadaver.

May 20—First subject, male cadaver. Diagnosis, tuberculosis. Common hat pins were used, and a pin thrust through the center of the percussion figure, then the abdomen opened. The kidneys were found nearly 1 inch lower than the percussion figure, their size corresponding to the figure.

May 23—Second subject, female. Diagnosis tuberculosis. Both kidneys downwardly displaced, lower pole about crest of ileum, one-half inch below percussion figure, which corresponded to size of kidney.

May 26—Third subject, male. Diagnosis, tuberculosis. Was injected with embalming fluid; kidneys were found corresponding in size to percussion figure and about one inch lower than the figure.

May 29—Fourth subject, male cadaver; diagnosis, tuberculosis. Percussion figure of right kidney small. After opening the abdomen this kidney was found imbedded in the intestines; turned at an angle and higher than percussion figure; not fixed by needles.

It will be noticed that the subjects examined had died of tuberculosis and were all emaciated. In one case we found both kidneys downwardly displaced. In all but the last one we found the projection upon the body wall higher than the organs after opening of the abdomen, suggesting that the organs were held in place by intraabdominal pressure, which, after opening, ceased to act. In no case had the needles fixed the organs, which suggested an insufficient technique.

In the fourth subject the percussion figure suggested a small kidney, which was explained by its position being turned and imbedded in the intestines. Prof. H. B. Gessner of Tulane University controlled the percussion, thrust the needles and opened the cadaver.

I discontinued these investigations when I left for Europe. In Berlin, Prof. Dr. R. Oesreich, Pathologist of the Royal Augusta Hospital, and Professor of the University of Berlin, offered his laboratory for continuance of these investigations. Strong, rigid steel needles, especially made for the purpose, were used. They were three cornered at the end and very sharp.

July 26—Female cadaver; very fat. Needles thrust through center of percussion figure, fixed the kidneys, which corresponded in size and location with projection figure.

July 26—Female cadaver; very much emaciated. Diagnosis, incarcerated hernia. A needle thrust through center of projection passed through center of kidney. Size of the organ corresponded to the percussion figure.

July 29—Male child, 1 month old. Diagnosis, bronchopneumonia. Cadaver opened, then kidneys felt and found 1 cm. lower than projection; size corresponding exactly to percussion figure.

July 29—Male child, 1 month only. Diagnosis, bronchopneumonia. Needle thrust through center of projection of right kidney. After opening, both kidneys corresponded to size of projection. Right kidney fixed in center by needle, left kidney 1 cm. downward displaced.

These last two experiments correspond to the results obtained with first three cadavers and were predicted by me. If the kidneys are not well fixed, opening of the cadaver will cause their prolapse.

Aug. 2—Cadaver of male, 45 years old. Diagnosis, contracted kidney. Immediate cause of death, pneumonia. Kidney fixed by needle. Projection small, kidneys exactly corresponding to projection.

Sept. 2—Male, 37 years of age, well developed. Diagnosis, Jacksonian epilepsy. Cyst in left half of brain. Kidneys fixed. Size and location corresponding to figure. Prof. Oestreich controlled percussion, thrust needles and opened the abdomen.

Sept. 4—Male, emaciated, 50 years old. Diagnosis, stomach and intestinal carcinoma. Abdomen distended and filled with large quantity of pus. Both kidneys fixed. They corresponded in size and location with percussion figure.

Sept. 5—Female child, 6 months old. Diagnosis, intestinal catarrh. Both kidneys fixed, and corresponded to percussion figure.

Sept. 8—Male, 40 years old. Well developed. Diagnosis, gangrene of leg. Kidneys fixed. They corresponded to the projection.

In the last three cadavers the kidneys were fixed and the abdomen opened, in the absence of Prof. Oestreich, by Mr. H. Bobe of his laboratory.

The method best adapted to prove on the cadaver the correctness of the percussion of the kidneys is by using the needles described. They were about 18 inches long, of strong steel, three cornered and sharp at the end. Thrust these needles through the center of the percussion figure till they project from the abdomen. The thrust, on account of the peculiar position of the organ against the spine, ought to be made with a slight outward angle, in order to penetrate the center of the kidney. The abdomen is then opened, the kidney palpated, removed, and measured.

Percussion is one of the cornerstones of diagnosis, and its application furnishes most valuable diagnostic results. Kidney percussion, which allows us to study the size of the organ, enables us, in Brights disease, to determine whether one or both organs are affected. The determination of the increase or decrease in bulk, through tumor or abscess of the kidney, is valuable. In nephroptosis it becomes especially valuable in obese subjects or patients with tense abdominal muscles, conditions which sometimes make it impossible to palpate the organ. In fact, there is hardly any disease in which a knowledge of size and location of the kidneys would not be of value.

These investigations on the cadaver call attention to the importance of intraabdominal pressure as a factor to keep the abdominal organs in place. This must be borne in mind when a laparotomy on thin patients is to be considered.

To sum up: By replacing the stroke with the drop in percussion, we have a method that enables us to make out with accuracy and ease the organs situated close to the body wall or deeply situated, the percussion lines corresponding sharply to the organs. We have a method superior to the usual method of percussion, in that it permits us to judge from the rebound of the hammer the change of vibrations and the percussion note at one and the same time, and especially that it eliminates largely the individual element and makes results uniform.

Further, according to the most prominent clinicians, kidney percussion has been impossible except in cases of very much enlarged kidneys, when it is for practical purposes useless. My methods give good results in kidney percussion under any conditions and with any patient, supplementing the diagnosis of the diseases of the kidneys and giving a ready and easy means to determine the actual size and location of the kidneys, which is of value in all cases, as stated before.

Again I will repeat that the drop is impossible unless the hammer is very lightly held.

It affords me great pleasure to thank my assistants, Dr. L. Fossier and Dr. Leon Lewis, also Prof. Dr. R. Oestreich of Berlin, Prof. Dr. H. Gessner of New Orleans, and Mr. H. Bobe of Prof. Oestreich's laboratory, for their kind and material assistance in this work.

KERATITIS EX ACNE ROSACEA.*

By WALTER BAER WEIDLER, M.D.,

NEW YORK,

MANHATTAN EYE AND EAR HOSPITAL, NEW YORK OPHTHALMIC AND AURAL INSTITUTE.

Concerning the various manifestations of Acne Rosacea affecting the eye very little has been written. Keratitis ex acne rosacea is rarely seen, especially in this country. Acne rosacea is a skin disease with which we are all familiar. Nearly always seen on the face, involving the middle two-thirds, it is a very chronic process as a rule, and when the eyes are affected we have a difficult condition to treat. The true etiology of acne is not well understood. I believe that the report of the following case will be found of great interest.

History.—Mrs. K. K., aged 42, family history negative. General health usually good. Has had three miscarriages. One son has trachoma. About twenty years ago, after the birth of her child, she began to have an eruption on the nose and face which was diagnosed and treated as acne rosacea. Eight years later acne began to involve the left eye. She was treated at this time with good results and was referred later to the skin clinic. Seven years ago she had a return of eye trouble and since then has had frequent attacks of keratitis. The patient presented herself for treatment at the Manhattan Eye and Ear Hospital on May 12, 1910. At this time the skin eruption was most marked. The edges of the lids were swollen and red, with intense photophobia and lacrymation. Right Eye: Pronounced injection of the bulbar and tarsal conjunctiva. The vessels in the bulbar conjunctiva were dilated and tortuous and extending on the cornea for about 6 or 8 mm., some of the vessels reaching the upper edge of the keratitis and then turning on themselves in small loops. Some of these return loops reached almost the corneal scleral margin again. These vessels and their looping may be plainly seen at the present time. The portion of the cornea involved by the process gave a reddish-grey reflex. A small chalazion was present at this time in the lower lid of the right eye, which was opened and curetted. Left Eye: The keratitis was much more severe and the destruction of the corneal tissue greater. This was the eye in which the keratitis had begun twelve years previously. The vessels were much larger and more numerous. The lower half of the cornea was rough

*Read at a meeting of the Section on Ophthalmology, Academy of Medicine, October, 1910.

and granular in appearance. The pupillary portion of the cornea was being encroached upon. The pathological changes seemed to extend into the deeper portion of the cornea. Vision, O. D. 14/200; O. S. 15/200. Wearing at the time—3.50sph., which gave 15/30 and 15/70. Urine negative. A von Pirquet vaccination test was made with the different strengths of tuberculin, using the crude 10 per cent. and a 50 per cent. solution, the result being negative. Later a Wassermann test was made, but this was also negative. After a month of treatment the patient ceased to report at the clinic. The face and eyes had cleared very nicely. The cornea of each eye was clean and the vessels were much smaller. After an absence of nearly two months she returned on September 15 for treatment, which had been discontinued. The face and eyes were about as they were when first seen in May, the left eye a trifle worse. Near the center of the cornea was a round, smooth, bulging area which looked as if it might perforate. Faint traces of staining about the edge were seen after fluorescein had been instilled into the eye.

Treatment.—The treatment in the first attack was boric acid wash, atropine for a few days, and hot compresses. Epsom salts were given in dram doses each morning before breakfast, and large doses of sodium salicylate, beginning with 10 grains four times a day and increasing five grains daily, the maximum dose being 60 grains per day. She was ordered to drink a glass of water every hour. The treatment of the second attack has been nearly the same as the first, omitting the atropine and using dionin instead, the maximum dose of the salicylate being 90 grains per day. The treatment was continued for some weeks and the eyes and face again became clear. I told my patient that she must not expect a cure of her eye trouble, that she must be prepared to have attacks from time to time, but that if she was careful to have them treated as soon as she found any recurrence of the disease she might be able to save enough vision for her household duties.

It would seem from the cases that have been reported from time to time that some reference would be found to this form of keratitis in the textbooks. I have been able to find only a brief reference in Norris and Oliver[1], in which the authors state that "acne of the face, nose, and cheeks may be accompanied by eruptions on the cornea which have the appearance of small phlyctenulæ. These eruptions of acne of the cornea are found only in persons who have passed the period of adolescence. They are accompanied by marked redness of the edges of the eyelids, are extremely rebellious to treatment, and are prone to relapse." Fuchs[2] speaks of acne rosacea of the conjunctiva, which was first described by Arlt, but makes no mention of it affecting the cornea. He calls attention to the fact that Horner was the first one to discover the analogy between chalazion and acne rosacea of the skin. In acne rosacea the sebaceous glands play the same part that the meibomian glands do in chalazion formation. Weeks mentions this form of keratitis in the last edition of his textbook, but gives very little attention to what should be regarded as one of the recognized forms of keratitis, which occurs more frequently than the literature of the subject would have us believe.

Keratitis rosacea is a process beginning as an acne of the conjunctiva and gradually extending and involving the cornea. With keratitis rosacea there is a very pronounced swelling of the conjunctival vessels together with the formation of new vessels. This is accompanied by a hyperplasia of the epithelial and subepithelial tissues. This being true, one is quite justified in calling this form of keratitis by the name above given. I have been able to find the report of fifteen cases of this form of keratitis[3]. It usually affects both eyes, and the degree of keratitis depends upon the severity and duration of the acne eruption on the face.

Acne rosacea is generally due to indiscretion of diet, inordinate use of alcoholic beverages, and intestinal disorders, as autotoxemias. In some cases uterine troubles have been given as the factor and this may be the cause more often than is suspected, as acne is more frequently seen in women in the proportion of 5 to 1. Two per cent. of the cases in hospitals and six per cent. of the cases in private practice seen by the dermatologists are acne. The pathology is somewhat vague. Some authorities believe it to be a trophic neurosis, while others consider it as an angioneurotic edema accompanied with paresis of the vessel walls.[4] The presence of chalazion in keratitis rosacea has not been as frequent as one might expect from the studies of Horner. In most of the cases reported it has been the exception. My own case was accompanied with a chalazion and on questioning the patient I found that there had been a number at different times. There was always a marked blepharitis. The condition of the cornea was much the same as described in the long standing cases, *i.e.* the lower portion being always affected first, with the presence of blood-vessels which were under the epithelium and were not seen in great numbers, with the presence of slight opacities with no marked tendency to ulceration at any stage of the disease and with the gradual loss of vision. In the progress of the disease I was unable to find much involvement of the lymphatics. The long duration of this disease coupled with the frequency of the attacks has led me to feel that the prognosis is as a rule bad. Several of the cases that have been reported ended in the vision being reduced to "motion perception."

Various forms of treatment have been tried with little success. In the conjunctival form of acne dusting powders, as calomel and aristol, have been used by Nuel and Fuchs. The actual cautery has been advised. Some have claimed to see good follow the use of subconjunctival injections. Curetting has been tried by Shirmer[5] in the three cases reported from his clinic in Greifswald. The use of dionin in a five per cent. solution has given more relief than the use of atropine. Holocain is well spoken of but was not used in the treatment of this case. It has been of great interest to me to follow the action of the sodium salicylate. The teaching has always been that sodium salicylate in large doses is not well tolerated by the stomach. There never was any gastric irritation at any time and when the dose was the largest the skin and eye lesions were least annoying. We tried tincture of nux vomica in doses as high as thirty drops three times a day and the improvement in the condition of the skin of the face and the eyes was not nearly so marked as it was under the use of the sodium salicylate. It seems to be the experience of the men that have seen and treated these cases of keratitis rosacea that they are very prone to recurrence, no matter what the treatment has been. In view of the fact that the derma-

tologists have not been able to find any treatment of acne that can be looked upon with any degree of certainty to cure the skin lesions, it is all the more discouraging from the ophthalmologist's standpoint.

This paper has been prepared with the hope that there may be an interest excited in these cases of keratitis rosacea. The diagnosis of this form of keratitis is as a rule not difficult because of the presence of the acne. The lids show the blepharitis marginalis and the tendency to chalazion formation. Both the bulbar and tarsal conjunctiva are affected by the process. There are phlyctenula-like eruptions on the conjunctiva and cornea, which phlyctenular eruptions become true infiltrations of the corneal epithelium, as a rule circumscribed, and going on to the stage when the epithelium is exfoliated and an ulcer is finally formed. These areas of superficial ulceration stain with fluorescein. This condition of the cornea is accompanied by an interesting and characteristic invasion of the cornea with blood-vessels. Some of these are the dilated bulbar conjunctival vessels, and some are of new formation. The blood vessels in my case presented a peculiar tendency to the formation of loops. I have tried to point this out in the history record, but should again like to place particular stress upon this peculiarity. Whenever there was the appearance of an infiltration of the cornea this peculiar formation of the vessels was noticed. The ulcers always underwent repair, but always with the formation of scar tissue at the site of the ulceration.

THE RECOGNITION AND TREATMENT OF GONORRHEAL URETHRITIS AND CYSTITIS IN WOMEN.*

By WALTER T. DANNREUTHER, M.D.

NEW YORK.

SURGEON, ST. ELIZABETH'S HOSPITAL AND ST. BARTHOLOMEW'S CLINIC.

Gonorrheal infection of the female urethra is a condition frequently encountered by the gynecologist, although acute urethritis is unusual and the chronic type often passes unrecognized by the general practitioner. Contrary to the apparent consensus of opinion, however, that the urethra is invariably the site of primary gonococcal invasion in women, statistics from the author's dispensary and private practice show that, in 65 per cent of cases, the cervix uteri is the seat of primary infection, and this cervicitis often exists without urethral involvement. These conclusions are based upon clinical evidence, subjective and objective, and careful microscopy. Nevertheless, gonorrheal urethritis is not uncommon in gynecological practice, and should be thoroughly searched for in all examinations of the female genitalia because of its chronicity and its being a constant element of danger to the patient and her immediate family. Owing to the absence of macroscopical manifestations, the diagnosis is difficult and depends almost entirely upon the microscopic findings. The excess of urethral secretion is often so slight that it is seldom regarded with suspicion or as a discharge by the patient or her physician. In exceptional cases ardor urinæ is an early and annoying symptom, for which the patient will seek relief. Palpation of the urethra through the vagina is useless as a diagnostic method, and is of service only in so far as the urethral stripping will express a sufficient quantity of secretion for microscopic examination.

*Read before the Tri-Professional Medical Society, New York City, November 15, 1910.

When a suppurative cystitis is associated with a gonorrheal urethritis and other causative factors, such as tuberculosis, *Bacillus coli communis*, traumatism, etc., have been eliminated, it is logical to assume that the bladder inflammation is due to gonococci. The inflammatory process is almost invariably restricted to the region of the trigone, and has been appropriately termed by Finger, urethrocystitis. Experience signifies that, at most, cystitis is but an infrequent complication, since it has been proven by Guyon and his school that microorganisms do not penetrate normal bladder epithelium without persistent predisposing factors. In the majority of cases of cystitis varying types of bacteria are present, and it is therefore extremely difficult to demonstrate whether or not the gonococcus is responsible for the infection. The catarrhal type is never due to pyogenic organisms, and consequently never results from gonococci, which are pus-forming bacteria. True Gram negative intracellular gonococci can be microscopically identified in the urinary sediment of but a small percentage of cases of suppurative cystitis because of the technical difficulties in securing a satisfactory and well-stained smear, so that the clinical conclusions are often difficult to prove.

The urethroscope and cystoscope may be of diagnostic and therapeutic service in all these cases. As instruments of diagnosis, one may verify the diagnosis and exclude other lesions; as therapeutic instruments, they permit of local applications. These diagnostic refinements are rarely essential, however, and may even do harm. In the presence of acute inflammation instrumentation is absolutely, and in chronic cases relatively, contraindicated because the irritation and traumatism caused thereby may aggravate the pathological condition.

With the burden of proof resting upon the microscope, this should be extended every opportunity of performing its functions properly. That is, have a trained eye above the eye-piece and an even, well-stained smear under the objective. A urethral specimen is best obtained by means of a little sterile cotton on an applicator, wiped within the meatus, and smeared and fixed on a cover glass. The specimen should, for obvious reasons, be obtained a few hours after the last urination. The urinary sediment may be obtained by either centrifugalization or by permitting the urine to stand for a few hours. Many pathologists object to the use of the centrifuge because the molecular agitation tends to break up and destroy such cellular inflammatory elements as may be present in the urine, especially the leucocytes. As in the male, failure to discover gonococci in the urethral secretion or the urinary sediment does not necessarily determine absence or elimination of the germs. *The presence or absence of gonococci can be demonstrated only after repeated microscopical examinations.*

While it is not within the scope of this paper to discuss the diagnosis of cystitis *per se*, two points

in connection therewith are worthy of mention. First, turbidity of the urine, which may be due to phosphaturia, albuminuria, bacteriuria, or pyuria. In all macroscopic urine examinations it is important that the urine be voided in the examiner's presence, since the urinary filaments readily dissolve. Phosphates may be eliminated by the addition of acetic acid; bacteriuria is not affected by heating or acidulation, and will be demonstrable by the microscope; and pus may be identified by the Donné test, which consists of adding caustic potash and rapidly twirling the tube containing the urine, whereupon the urine body clears and the pus precipitates as a ropy mass. Secondly, the diagnosis may be made by microscopical uranalysis. Large numbers of bladder epithelia, particularly those from the middle and deep layers, together with pus corpuscles, establish the diagnosis of cystitis.

Having recognized the exact pathological changes in a given case, we come to a consideration of its treatment. This is best carried out in the office of the physician, except in those instances in which there exists a suppurative cystitis. Only the acute stage of vesical inflammation requires confinement to bed for a day or two. Cleanliness of the intestinal tract is important and should be maintained by dietary restrictions and the employment of mild salines. Two drams of sodium phosphate dissolved in a glass of vichy taken each morning before breakfast will be found pleasant and efficient for this purpose. Alcohol in any form must be rigidly prohibited in all cases of urethral or bladder inflammation. Scrupulous cleanliness of the external genitalia is necessary to avoid autoinfection. The urine may be diluted and rendered bland by copious draughts of clear water, and the destruction of bacteria facilitated by the administration of ten grains of salol and ten grains of hexamethylenamine three times a day. The daily dose of the latter should never exceed thirty grains a day, or burning and frequent urination may result, as the writer has learned, unfortunately, by experience.

The most satisfactory method of controlling gonorrheal infections of the lower urogenital tract consists of irrigations with a watery solution of a reliable antiseptic. The bladder should be empty and the urethral crypts and Skene's glands freed of secretion by gentle massage through the vagina from within outwards. Either a Valentine apparatus or an ordinary fountain syringe may be utilized for irrigating, provided that the glass tip held against the meatus is slightly longer and more pointed than the nozzles intended for the male. If the urethra alone is to be irrigated, the reservoir is elevated only two or three feet above the level of the patient, to avoid forcing the solution beyond the sphincter; but if there is a concomitant cystitis and an intravesical irrigation is desired, the reservoir should be raised higher, so that the hydrostatic pressure will overcome the muscular constriction at the neck of the bladder. A quart of warm solution (from 100° to 104° F.) is usually sufficient for all practical purposes. A saturated solution of boric acid is preferable for the acute cases, because it is mild and unirritating and does not cause the patient discomfort or pain. When the inflammatory reaction has somewhat subsided in the acute cases and in all subacute and chronic cases the employment of iodine yields brilliant results. Since the publication of the author's first papers, three years ago, on the germicidal action of iodine,* numerous laudatory articles have appeared from the pens of other writers, both in this country and abroad, so that its surgical value is now firmly established and universally recognized. Iodine is particularly applicable in gonorrheal infections of the urethra and bladder by virtue of its powerful stimulating and penetrating properties, so that its efficacy is extended to the submucosa. Other factors in its favor are that it does not irritate or coagulate albumin, as do bichloride of mercury and silver nitrate, and is not decomposed by urine, as are the organic salts of silver. Occasionally, however, silver nitrate is of service in protracted cases. The exact strength of the iodine solution will depend upon the acuteness of inflammation, the toleration of the patient and the physician's judgment, but usually varies from a half a dram to a dram of the tincture to a quart of water. The proportion of iodine should be increased in inverse ratio to the inflammation present. Irrigations are given daily until the gonococci disappear, and then continued every other day until ten consecutive negative specimens have been obtained.

Areas of erosion that prove obstinate yield promptly to direct applications of a 5 per cent nitrate solution. Stricture of the female urethra is an uncommon condition, but does occur occasionally. Dilatation may be accomplished up to 26 or 28° F., by means of Pratt's female urethral sounds, but the greatest care should be exercised during the manipulations that the sensitive and delicate urethra is not injured.

In conclusion, the author would suggest and urge that the examining physician, be he specialist or general practitioner, should consider every female urethra infected until proven otherwise by the microscope, irrespective of the lack of symptoms or the patient's apparent respectability. By so doing he will fulfill his duty to the patient and her family and will make no errors of omission.

2030 Broadway.

THE CLINICAL VALUE OF BLOOD PRESSURE STUDIES.†

By FRANCIS ASHLEY FAUGHT,

PHILADELPHIA.

The blood pressure test is now firmly established and is entering more and more into general everyday use as a diagnostic method of great value.

We recognize this test as valuable in the diagnosis of certain diseases and as a dependable guide in prognosis and treatment. The present standing of the test has been evolved from innumerable observations out of which have been developed certain fundamental facts. These studies have covered almost every conceivable physiological state and pathological condition.

Unfortunately, the many so-called physiological factors which may and do continually cause minor variations in our readings in the same patient from time to time, and the differences resulting from varying technique or the employment of different forms of instrument, all make impossible the adoption of fixed and absolute figures with which to

*The Surgical Value of Iodine: Medical Record, January 25th, 1908. The Practical Value of Tincture of Iodine and Iodine Catgut in Major Surgery: Medical Record, January 16th, 1909.

†Read before the Philadelphia County Medical Society October 26, 1910.

separate the normal from the pathologic. Chief among these physiological influences is the age factor which must enter more or less into all determinations.

In order roughly to measure the effect of age upon the reading in a given case I have adopted a factor which computes the elevating influence of advancing years, and which for practical purposes gives a result conforming closely to the figures given by the majority of observers.

Rule for determining the average normal systolic blood pressure. At age twenty consider the average normal systolic pressure to be 120 mm. Hg. For each year of age above this add one-half of one millimeter pressure.

Thus, at age twenty-five the pressure would be 122½. At age forty, pressure 130, etc.

The blood-pressure test finds its widest clinical application in the study and treatment of cardiovascular and renal diseases. Here it may be the most important sign in establishing firmly the diagnosis of chronic interstitial nephritis; also, on the other hand, it may be the pivotal sign which indicates a passing renal disturbance of toxic or metabolic origin, often showing the same urinary picture as a chronic interstitial, from a permanent renal change. In this relation the test is extensively employed by insurance companies.

In the study of myocardial conditions we may be aided in arriving at a diagnosis and also in forming a more accurate prognosis. This by means of the work test. Such a study will materially aid in advising these patients as to the amount and duration of exercise which may be indulged in without great danger.

In the treatment of all cardiovascular and renal conditions we have here a simple and accurate means of following from day to day the changes in a dangerously high pressure, and the efficiency of treatment will be enhanced by our ability to quickly note the activity of drugs or other measures which may be employed. The possibility of placing dependence in doubtful and inert drugs is at the same time removed. The danger of causing a too rapid or too great reduction in pressure is likewise also prevented.

In detecting the toxemias of pregnancy Hirst (John Cooke Hirst, *New York Medical Journal*, June 11, 1910, p. 1,024) has shown that in this test we have a method of greatest value, possibly ranking above urinalysis. He says: "The earliest and most constant sign of toxemia in the latter half of pregnancy is a high and constantly rising blood pressure; this symptom precedes the albuminuria and all constitutional signs of impending eclampsia." Other investigators bear witness to the facts.

In the field of tropical medicine Rogers has found (Leonard Rogers, *Therapeutic Gazette*, November 15, 1909) this test a reliable guide for the need of intravenous administration of salt solution during the stage of collapse in cholera.

In surgery the safety of anesthesia is increased by the routine use of the test during all prolonged and extensive operations. Thus the approach of dangerous shock is early detected and the need for stimulation or the speedy termination of the operation indicated.

As a guide for venesection, saline infusion, or the Murphy treatment, the sphygmomanometer is invaluable since it gives an accurate report of the state of blood pressure and through it that of the circulation at all times.

Recently ophthalmologists have appreciated the great value of this test in the study of diseases of the eye, particularly before certain operative procedures.

Life insurance companies now employ the observation upon an ever increasing number of applicants, the standardization of risks being greatly facilitated thereby. (Francis Ashley Faught, *New York Medical Journal*, July 23, 1910.)

I regret that time will not permit me to go more into detail regarding the ever widening field of application for this test, but before closing let me say that as time passes I become more and more fully impressed with the fact that I cannot do without the sphygmomanometer and that I find it valuable in a large number of cases where in conjunction with other diagnostic and laboratory methods the assistance derived from it is often greater than any other test at our command.

1831 Chestnut Street.

Importance of Radiography in Estimation of the Amount of Injury Produced by Accidents of Workmen.—Saverio Acampora calls our attention to the value of the *x*-rays in determining the actual injury sustained in accidents of labor, in relation to the adjustment of damages for employers and insurance companies. In illustration of this fact he gives us the history of an interesting case of a workman in a factory who, while working on a heavy wagon, had his foot injured by the falling of a heavy wheel on it. The result was a fracture of some of the bones of the foot, which were set in the usual way. The patient was a healthy young man, with no bad heredity, and yet when he went back to work he found himself unable to endure the standing and the strain of his work on account of pain in his foot. The *x*-ray picture showed that there was an ununited fracture of the second metacarpal bone, which had formed a pseudarthrosis for itself, the two fragments not being in the same line. Thus, when he stood, the fragments were not in the natural position, and much pain was created, and a certain deformity remaining was accounted for. Thus the *x*-ray picture demonstrated a reason for an unexpected amount of disability that demanded larger damages.—*Annali di Elettricita Medica e Terapia Fisica.*

Umbilical Hernia with Cardiac Ectopy.—Kirmisson divides hernia at the umbilicus into three varieties, according to the period of its appearance. Embryonic hernia occurs within the three first months of fetal life, and is due to a failure of development of the ventral plates which never close. Such a hernia has no skin envelope, and is covered by a thin membrane derived from the amnion, an internal serous membrane, and a gelatinous substance between. The liver is often seen in the tumor, which has no sac. The author reports a case of this variety in which the heart was almost vertical in position. The second type of congenital hernia occurs in the later months of fetal life; it is covered by the skin, and has the regular number of envelopes; it is due to the nonadherence of the ventral plates at the umbilicus. This form is much less serious than the other. In a paper by Berger, 32 operations are cited, with 26 cures and 6 deaths. The third form is the ordinary one that is seen often in weak, premature infants, being of small size, at the navel. Its treatment should be undertaken by placing a proper pad and bandage about the body, to be worn for less than four years at the most. If a spontaneous cure has not taken place by that time operation is in order.—*Le Bulletin Médical.*

The Histological Diagnosis of Rabies.—Diaz Triana states that Cajal's method affords greater exactness than either von Gehutchen's or Negri's. Von Gehuchten's method consists in the discovery of a proliferation of the endothelial cells of the capsule of the nervous element, which proliferation takes the place of the protoplasm and nuclei. Cajal's method not only affords greater security but also brings out very clearly the characteristic lesions of rabies in three hours, and it is so exact as to be present in all positive cases. The lesions described by Cajal consist in striking hypertrophy of the neurofibrils of the nerve-cells, and also in the disintegration and scattering of the chromatic spherules of the nucleoli. Cajal's method is that of double argentic impregnation and has greater advantages than any others for experimental diagnosis.—*Crónica Médico-Quirúrgica de la Habana.*

MEDICAL RECORD.

ACUTE INTESTINAL TOXEMIA IN INFANTS.

ALTHOUGH summer diarrhea is one of the most fatal diseases of early life, its actual causation has never been determined with scientific precision. Hot weather and an impure milk supply have been vaguely associated with the heavy infant mortality of summer, but the immediate pathogenic agent has escaped detection. The definite isolation of this agent would be a discovery of far-reaching importance in preventive medicine.

Apparently a great stride in this direction has recently been made. In an experimental investigation of the etiology and pathology of epidemic diarrhea, Ralph Vincent of London* has obtained tangible results. On the basis of the experimental production of the disease in animals and the study of the post-mortem conditions, both gross and microscopical, this investigation has enabled him to draw the following conclusions: Acute intestinal toxemia is a disease directly caused by the absorption of poisons produced by the action of certain microorganisms whose normal function is the dissolution of dead organic material. The organisms, while always present in the healthy alimentary canal, are, under normal conditions, quite unable to carry out this function, since they are inert in an acid medium. The essential cause of the disease is the inability of the infant to protect itself from the action of these organisms, owing to its food being so altered from its normal character that the necessary supply of lactic acid cannot be maintained. As soon as this supply fails the disease arises. The disturbance involved in such a radical alteration of the normal conditions produces a more or less violent diarrhea, but this diarrhea is not an essential process of the disease, and may be marked in the least severe cases and entirely absent in the most rapidly fatal. It is extremely important in regard to the disease that its two diagnostic features should be recognized—an alkaline reaction of the contents of the alimentary canal and toxemia. For there are many other conditions giving rise to diarrhea, while there is one condition which is the exact opposite of intestinal toxemia, namely, the diarrhea caused by the excessive production of acid. The former is profoundly dangerous, for it is caused by a powerful poison circulating in the blood; in the latter condition a normal constituent of the intestinal contents is present in abnormal amount. This excess can only become dangerous if it be allowed to continue for such a long period that the continued diarrhea produces a degree of exhaustion endangering life.

The microorganisms concerned in the production of the disease, with one exception (the *Bacillus proteus vulgaris*) have all been isolated from raw and boiled milk, from condensed milk, and from agar plates exposed to the air in various places and under different circumstances. Not being pathogenic organisms, they are not described in detail in the usual text-books and have received but little attention in comparison with the organisms associated with the production of specific diseases. These organisms belong to the "mesentericus" group, which is a very large one, including many varieties of bacteria. These are commonly found in the intestine, but there is nothing to indicate their special connection with the intestinal canal for, in normal circumstances, they pass through this without exerting any influence. The two commonest organisms actually producing putrefactive changes in boiled milk are the *Bacillus subtilis* and the *Bacillus mesentericus vulgatus*. They are practically always present and are the chief representatives of this group of organisms in reference to the putrefactive changes occurring in milk.

The determining point in the incidence of acute intestinal toxemia is the failure of the stomach and the intestine to maintain the acid reaction of their contents. Directly this fails the putrefactive organisms proceed to live and develop actively in the alimentary canal. A complete revolution of the normal process is thus attained. Being actively motile, the metabolism of these organisms is rapid and extensive, and the immediate products of their metabolic activity are absorbed from the intestine and produce paralysis, coma, and death in the individual attacked.

Vincent alludes to the experience of the Infants' Hospital of London, whose work is confined exclusively to infants under twelve months of age. No attempt is made to isolate cases of epidemic diarrhea; these are kept in the same wards with other patients, none of whom has ever contracted the disease in the hospital. There is pointed out the remarkable correspondence between the poor breast-fed baby of the London slums and the infant warded in the hospital—both are fed on a pure *raw* milk. Vincent says that the infants at the hospital are protected by something much more powerful than isolation, for he contends it is a practical impossibility for epidemic diarrhea to occur in an infant fed on fresh milk. It is essential for the development of the disease that the characteristic properties of the natural food should have been destroyed by heat, by preservatives, or by some other means. Vincent's experiments undoubtedly confirm the beneficent rôle of the lactic acid bacillus normally present in raw milk, and the happy results attending the use of buttermilk in cases of summer diarrhea.

In discussing the prevention of acute intestinal

*"On Acute Intestinal Toxemia in Infants." London: Baillière, Tindall & Cox, 1911.

toxemia, Vincent concludes with the paradoxical statements: The dirtier the milk the more important is it that it should not be cooked; boiling the milk utterly destroys the balance provided by Nature; milk that has been boiled is not milk; fresh raw milk is the fundamental requirement of the infant, essential to its peculiar digestive and nutritive needs. The theory of Vincent would be of greater practical importance were it possible to secure pure raw milk in all cases. The feeding of babies on dirty milk would be monstrous, and fortunately there are few to-day who would refuse the safeguard furnished by pasteurization.

THE RELATIVE ABSORPTION OF SOLAR HEAT BY OLIVE-DRAB AND KHAKI.

The board for the study of tropical diseases in the Philippine Islands recently sent a report to the Surgeon-General, U. S. A., relating to experiments made under its direction on the relative absorption of solar heat by olive-drab and khaki-colored drilling. The report is published in the *Military Surgeon*, January, 1911. For long it has been the belief, founded on wide experience, that in order that a person may withstand the sun's ray with the least amount of danger and inconvenience he should be clothed in garments white or as nearly white as possible. This deduction is based also on the principle of physics that the absorption of solar heat is least for white material and increases through a definite series of colors up to black, for which it is at its maximum. This experience and scientific facts go to show that white garments are the coolest in hot weather. But white garments are for a variety of reasons not best suited to average military conditions, and, therefore, the object of military authorities is to discover which colored garments are, next to white, most fitted for the use of soldiers serving in tropical countries. Naturally, gray comes close to white in possessing slight absorptive power, and Notter and Firth have stated that khaki drill stands next to gray in this respect and appears to answer very well for a clothing material in the tropics. Woodruff advises white, gray, or yellow for outer clothing of those exposed to the direct rays of the tropical sun, while Munson is of the opinion that the dusty-brown "as exemplified by our khaki clothing" is the color "probably best answering both sanitary and military requirements under all circumstances."

The experiments referred to in the report were carried out solely with the view of discovering the color best adapted for the wear of the soldier exposed to the rays of the sun. When exposed to the direct rays of the sun the temperature beneath olive-drab material, starting at atmospheric temperature, rapidly rose as a result of heat absorption and after the lapse of an hour or more reached figures from 105° F. to 126° F. The atmospheric temperature remained unchanged. On the other [illegible] white drilling the temperature never [illegible] 101.1° F. and was usually below body [illegible]. The results of these experiments show [illegible] influence color has and how little influence is exerted by the natural atmospheric temperature in the tropics. There was little difference in the weight of the two materials which the men wore when the experiments were being undertaken. The inferences drawn from the experiments were that a material of olive-drab color absorbs much more solar heat than does the khaki-colored fabric, and the capacity of the darker material as a heat absorber is more marked with a bright sun than with dim sunlight. In the words of the report, "It cannot be doubted that, as compared with khaki, an olive-drab uniform will put a greater strain upon the heat regulating mechanism, the dissipation of the excess of heat being accomplished by greater evaporation of perspiration and greater respiratory action. The thermolysis will be accomplished mostly by more profuse perspiration. This will throw more work on the skin and heart, will increase the necessity for the ingestion of fluids and may lead to renal and bladder irritation from a too concentrated urine. "With white drill garments there is no fear of such happenings, since the temperature beneath the material is rarely above 98.6° F."

The experiments mentioned above seem to have proved most definitely that the khaki color is far superior to olive as a protection against the direct rays of the sun. It has been argued that protection against chemical rays is also needed. The report states quite truly that this has not been conclusively demonstrated and that it might not be gained by using darker outer garments. It appears that a new olive gray uniform material is being supplied to the army. It might have been wiser on the part of the military authorities to have waited until the results of such experiments as are detailed in the report had been known before ordering uniforms of this color. Of course, to a large extent, the comfort and health even of the soldier must be subordinated to military exigencies, and if it be true that the olive-drab uniform is better suited to active service on account of its comparative invisibility then a great deal is to be said for its retention. This point, however, should be made clear. From the purely sanitary point of view both helmets and uniform of those serving in the tropics should be of as light a color as is possible.

Diabetes and Tumor Formation.

It was noted years ago by Manders and others that diabetes and cancer occurred side by side in the same family trees to a degree greater than coincidence could explain. The discovery that malignant tumors were at times rich in glycogen also led Manders to look upon cancer as a "local diabetes," curable in theory by a diastatic enzyme. Later it was shown that the glycogen in tumors was not connected with their pathogenesis and had little significance of any sort. Quite recently Hirshfeld, in the *Berliner klinische Wochenschrift* for December 19, has called attention to a certain relationship between diabetes and neoplasiæ of the female genitals, including the normal hyperplasia of the gravid uterus. The claims advanced for the existence of this association are as follows: Pregnant diabetic women show a diminished tolerance for carbohydrates, and this loss may not be re-

gained. Genital tumors often develop at about the time of inception of diabetes, as if the former were able to influence unfavorably the carbohydrate metabolism. Cutting down the carbohydrates will sometimes diminish the degree of hemorrhage from uterine myomata. Again extirpation of these tumors—uterine fibromyomata, ovarian cystomata—will often cause improvement in a diabetic patient. Glycosuria may disappear outright or persist to a limited degree. Now it appears reasonable to regard this association of tumors with diabetes as not wholly foreign to the older views of Manders and others. The association may seem far-fetched, but we perceive vague intimations that certain tumors may be "diabetic equivalents." We have here little more than a "clue," but the pursuit of it may lead to something worth the time spent.

Crusade for the Prevention of Insanity.

Crusades against one or another evil seem to be the order of the day in all parts of the world. The crusade against consumption has been attended with a considerable amount of success both on the continent and in Great Britain. In order to enable a campaign against a widespread disease to bring about favorable results the iniatory process must be educative. Unless the population at large can be made to understand the reasons for the fight the ultimate outcome will not be satisfactory. So far as pulmonary tuberculosis is concerned educative measures have made their influence felt, and the consequence is that there is now ground for hope that the disease may be rendered far less harmful than is at present the case. Insanity is said to be on the increase throughout the world and to some extent this statement is true. In order to curb insanity a crusade conducted on intelligent lines, that is mainly educative, should be valuable. Such a crusade is contemplated by the State Charities Aid Association of New York. A special committee of that body on mental hygiene but recently announced the commencement of a State-wide campaign of education on the causes of insanity. This laudable enterprise is, of course, worthy of high commendation, but education as to the causes of insanity must be conducted with much discretion. There is no subject concerning which there are more diverse opinions than on the causes of insanity. However, there is one probably potent cause of insanity, the venereal diseases, regarding which education amongst the masses is sorely needed. It is stated that venereal diseases are not only rampant in this country, but increasing. Perhaps if knowledge relating to the maladies were more generally diffused their spread would be checked. The crusade against these diseases and against other causes which may induce insanity should, if wisely carried on, be productive of nothing but good.

News of the Week.

The Blackwell Memorial.—At the meeting held on January 25 in the New York Academy of Medicine, in honor of Elizabeth and Emily Blackwell, one of the speakers was Dr. Stephen Smith, who was a fellow student of Dr. Elizabeth Blackwell at the Geneva Medical College sixty years ago. Dr. Alice Stone Blackwell, a niece of the two physicians, gave some personal reminiscences of her aunts, and among the other speakers were Mrs. Henry Villard, Dr. William H. Welch, Dr. Abraham Jacobi, Dr. Emma B. Culbertson, and Dr. Gertrude B. Kelly.

American Medical Association.—Complaining that the American Medical Association has been run as an "autocratic and despotic corporation," Dr. G. Frank Lydston has begun a suit in Illinois to compel State Attorney Wyman to start ouster proceedings against the trustees of the Association. The chief contention in the suit is that the election at which these trustees obtained office was illegal as it was held in St. Louis, whereas the Association is an Illinois corporation. The Attorney-General had previously refused to enter into the proceedings, so that a suit to compel him to do so was the only means open to those seeking to oust the trustees.

Sleeping Sickness.—The Army Medical Museum at Washington has received a collection of flies and mosquitos and many photographs intended to illustrate the origin and spread of the "sleeping sickness" in Africa. The work has been done by Major W. M. Roberts of the United States Army, who during four months' leave of absence has been traveling in Northern Africa making an investigation of the disease.

Plague in China.—The Chinese Government, realizing the gravity of the situation, has begun active measures for the suppression of the plague, and has written to its foreign ministers instructing them to invite the Governments to which they are accredited to send experts to the affected districts to study the disease. The worst center of infection appears to be Fudziadian, a suburb of Harbin in Manchuria, where as many as 1,500 deaths were reported in one week, and this town is now to be isolated as far as possible. On January 26, 160 deaths occurred at Harbin and 60 at Mukden. Cases also continue to appear in Pekin and many of the foreign legations have been closed.

Registration of Births.—In New York the Department of Health has begun and will continue a strict enforcement of the section of the Sanitary Code which requires physicians and midwives to keep a record of the births in which they assist professionally, and to file a written copy of the record of each birth with the Department of Health within ten days thereafter. Cases of flagrant violation are now referred to the Corporation Counsel for prosecution, and from October 27, 1910, to January 18, 1911, the Department was successful in thirty-five actions which were begun in the Municipal Court or settled out of court. About fifty additional cases are now pending. The United States Bureau of the Census is also agitating the question of procuring better registration of births throughout the United States. It is pointed out that other nations are far ahead of this country in this respect and that, in fact, there is not a single State which has a complete registration of births.

Tuberculosis Day.—April 30 has been named this year as "Tuberculosis Day," and will, it is hoped, be generally observed in churches throughout the country. The National Association for the Study and Prevention of Tuberculosis is planning to have ready a mass of statistics for the use of the clergy in presenting the matter to their flocks.

Scarlet Fever Along the Hudson.—An epidemic of scarlet fever has occurred in many of the towns of the lower Hudson River Valley, N. Y. Yonkers, Tarrytown, Ossining, and Peekskill all report a number of cases of the disease. Although investigations are being carried on the source of the infection has not yet been determined.

City Milk Depots.—At a meeting held in the Academy of Medicine, on January 27, Commissioner Lederle of the New York Department of Health announced that the city was prepared to spend $40,000 in the establishment of fifteen stations for dispensing pure milk for infants, and that all would soon be opened.

Cholera in Arabia.—An outbreak of cholera is reported among the recruits recently sent from Constantinople to Hodeida, Arabia, to reinforce the Turkish troops fighting the rebellious Arabs in the Yemen district. As Hodeida is the base for the Turkish operations and the station for supplies, the difficulties of quelling the insurrection are likely to be greatly increased by the outbreak of the disease.

Mt. Sinai Hospital.—The 58th annual report of Mt. Sinai Hospital, New York, shows that during the past year 7,613 patients were treated in the hospital and 2,056 in the accident ward. In the seven months that the dispensary has been open, 49,426 patients were treated. Receipts for the year were $426,138.58, and the deficit was reduced to $10,803.76. The legacies and bequests received during the year amounted to $73,762.07, and $52,000 was donated for the endowment of beds. The pathological laboratory is soon to be enlarged, and the *x*-ray department will be ready by the middle of February. The arrangements already in force by which the students of the College of Physicians and Surgeons are admitted to the hospital for clinical instruction will probably soon be extended so as to include students from the University and Bellevue Hospital Medical College.

Pasteurized Milk Inquiry.—The Department of Agriculture and the Public Health and Marine-Hospital Service have been asked to undertake an examination into the relative value of raw and pasteurized milk for the feeding of children. The request is made by the Committee on the Study and Prevention of Infant Mortality of the Monday Evening Club of Washington.

Dr. Thomas W. Salmon, formerly stationed at Ellis Island, has been appointed a member of the Board of Alienists under the New York State Lunacy Commission, and examiner of immigrants with mental defects. He is now in the United States Marine Hospital at Chelsea, Boston.

Dr. Alfred Stengel has resigned as visiting physician to the Philadelphia General Hospital and he has been succeeded by Dr. William Pepper.

Philadelphia Medical Club.—At the annual meeting, held January 20, the following officers were elected for the ensuing year: *President*, Dr. Wm. L. Rodman; *First Vice-President*, Dr. S. Lewis Ziegler; *Second Vice-President*, Dr. Gwillym G. Davis; *Secretary*, Dr. J. Gurney Taylor; *Treasurer*, Dr. Lewis H. Adler, Jr.; *Governor for five years*, Dr. Edward L. Duer; *Directors for one year*, Drs. Wm. E. Darnall, McCluney Radcliffe, John W. West, Charles A. E. Codman, and Judson Daland.

Harvey Society.—The fifth lecture of the Harvey Society will be given by Dr. Thomas B. Osborne of the Connecticut State Agricultural Experiment Station, at the New York Academy of Medicine on Saturday evening, February 4. The subject of the lecture will be "The Chemistry of the Proteins."

Animal Clinic at Cornell.—Dr. Frederick Gwyer, Professor of Operative and Clinical Surgery in the Cornell University Medical College, New York, announces the reopening of the animal hospital and dispensary connected with the College, which after a brief time of activity was suspended a while ago because of lack of funds. All treatment of animals taken to the clinic is free.

Mme. Curie Fails of Election.—In spite of the widespread interest expressed in her candidacy, Mme. Curie was not successful in the election held on January 23, to fill the seat in the Académie des Sciences, once occupied by her husband. The great obstacle to her election was her sex, the Institut de France having spoken against the admission of women. The seat was won by M. Edouard Branly, the author of many works on physical science and electricity, who received 30 votes to Mme. Curie's 29.

Street Car Accidents.—The Public Service Commission reports that 48,013 persons were injured in accidents on the various surface roads throughout the five boroughs of New York City during 1910, of whom two-thirds were passengers, one-sixth pedestrians, and one-sixth employees. Of the total number of accidents, 2,874 were serious, 377 being fatal. In addition, 72 persons lost a limb, and 379 suffered broken limbs.

Charitable Gifts.—The Lutheran Hospital of Eau Claire, Wis., has received $30,000 from the estate of the late Sigvald Quale, who died recently.

The Presbyterian Hospital of New York receives $5,000 by the will of the late Mrs. Lord to be used for the endowment of a bed in memory of Franklin B. Lord.

The Norwegian Hospital of Brooklyn has received a gift of $15,000 for its endowment fund from Mr. Jens Skougaard of Christiania, Norway, who was formerly president of the Board of Managers of the hospital.

Association of American Medical Colleges.—The twenty-first annual meeting of this association will be held in Chicago at the Congress Hotel, February 27 and 28. The association will consider for adoption the report of the curriculum committee submitted last year, and any amendments which may be proposed, such as the more perfect regulation of the administration of entrance requirements and the elimination of conditions. The report of the committee on pedagogics will consider some very essential phases of medical teaching. The report of the committee on education will contain many recommendations for action. Papers will be read by the following: "Requirements for admission to the Medical Course," Geo. E. MacLean, President, University of Iowa; "The Fifth or Hospital Year," Dr. F. F. Wesbrook, University of Minnesota; "Administration of Entrance Requirements," Dr. B. D. Harison, Michigan State Board of Registration in Medicine; "The Medical Library," Dr. C. M. Jackson, University of Missouri; "Unity of Purpose, Unity of Action," Dr. J. A. Witherspoon, Vanderbilt University. The secretary is Dr. Fred C. Zapffe, 3431 Lexington street, Chicago.

The Newark Medical League held its annual banquet on Jan. 26, 1911, one hundred and sixteen physicians being present. Dr. Robinson read a paper on "The Improvement of the Human Race," which was discussed by Drs. E. J. Ill, S. E. Robinson, T. M. Gray, W. H. Hicks and D. E. English. The following officers were elected for the ensuing year: *President*, Louis Weiss; *vice-president*, Edwin Steiner; *treasurer*, Louis S. Davidson; *secretary*, Abraham Finkelstein.

The Late Dr. Bradshaw.—At a meeting of the

Lenox Medical and Surgical Society, held January 28, the following minutes were adopted:

"It is with feelings of profound sorrow that the Lenox Medical and Surgical Society is called upon to record the death of one of its members, Dr. L. L. Bradshaw, who died at his home on January 9, 1911, in the 58th year of his age. In his death the society is bereft of one of its most honored and respected members. As one of the founders of the society he had always taken a most active interest in its welfare, contributing much to its success by the value of his vast experience and the sweetness of his companionship. His professional career was characterized by a conscientious appreciation of duty and an unfailing fidelity to the welfare of his patients; and to the poor and needy he ministered with a most loving and unstinted devotion. His personal character was marked by a high sense of integrity; he possessed a most sunny disposition, with patience in his sufferings and always showed charity and loyalty toward those with whom he was associated.

"Be it *resolved*, that these resolutions be recorded in the transactions of the society, that they be published in the Medical Record, and that a signed engrossed copy be sent to the family of our late beloved member." (Signed) W. K. Simpson, M.D., J. Lee Morrill, M.D., H. H. Seabrook, M.D., *Committee*.

The Late Dr. Kipp.—At a meeting of the Visiting Staff of the Mountainside Hospital, held January 19, 1911, the following resolution was adopted: *Resolved:* That the members of the Visiting Staff have heard with great regret of the death of Dr. Charles H. Kipp, who had been consulting oculist and aurist to the hospital for fourteen years. Dr. Kipp's renown in his special field of work is well known, and it is a pleasant duty to state that he was always most willing to give the members of the staff the benefit of his knowledge and experience whenever called on. He was always interested in the work of the hospital and for some years gave lectures to the nurses on the care of cases of eye and ear disease. By his death the hospital has been deprived of a valuable consultant. *Resolved:* That this resolution be spread on the minutes and copies sent to the Medical Record and the *Journal of the Medical Society for New Jersey*. Henry B. Whitehorne, M.D., Richard P. Francis, M.D., *Committee*.

Obituary Notes.—Dr. Henry Crippen Neer of Park Ridge, N. J., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1860, a member of the New Jersey State and Bergen County Medical Societies and of the American Medical Association, died in the Hackensack Hospital of cancer, on January 27, aged 72 years. He was born in Schoharie County, N. Y., and practised in Bergen County, N. J., for forty-five years. He was a non-resident fellow of the New York Academy of Medicine and at one time president of his County Society.

Dr. William S. Ely of Rochester, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1867, a member of the American Medical Association, the New York State and County Medical Societies, the Rochester Pathological Society, and the Rochester Academy of Medicine, attending physician to the Rochester City Hospital, and a veteran of the Civil War, died at his home on January 15.

Dr. John W. Gould of Newark, N. J., a graduate of the Albany Medical College in 1880, died at his home on January 16 after a brief illness, aged 72 years.

Dr. Joseph H. Hunt of Newton, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1873, formerly a practicing physician in Brooklyn, and a member of the Board of Education of that city, and first president of the Department of Mineralogy of the Brooklyn Institute, died at his home on January 15, aged 70 years.

Dr. William E. Curd of Copan, Okla., a graduate of the Medical Department of the University of Nashville, Tenn., in 1900, a member of the Oklahoma State and Third District Medical Societies, died at his home of typhoid fever on January 11, aged 37 years.

Dr. Warren G. Priest of St. Louis, Mo., a graduate of the Washington University Medical School of St. Louis in 1878, and formerly connected with the City Hospital, died of tuberculosis on January 11, after a long illness, aged 56 years.

Dr. David M. Miller of Indian Springs, Tenn., a graduate of the College of Physicans and Surgeons of Baltimore in 1887, died at his home on January 8, aged 70 years.

Dr. F. L. Crandell of Denver, Col., a graduate of Rush Medical College in 1882, formerly a police surgeon of Chicago, died at his home of pneumonia on January 5, aged 50 years.

Dr. Edwin Lacy Gibson of Staunton, Va., a graduate of the University of Maryland School of Medicine, Baltimore, in 1894, and a member of the Virginia State and Augusta County Medical Societies, died at his home of typhoid fever on January 8, aged 50 years.

Dr. Louis A. Querner of Cincinnati, Ohio, a graduate of the Medical College of Ohio, Cincinnati, in 1867, formerly coroner of Hamilton County and a surgeon of the Cincinnati Fire Department, died at his home after a long illness on January 7, aged 65 years.

Dr. Charles Heil Hunsicker of Philadelphia, Pa., a graduate of the Jefferson Medical College in the class of 1900, and later resident physician in the German Hospital of Philadelphia, and associate in surgery in the Jefferson Medical College, died of intestinal disorder at his home on January 9, aged 34 years.

Dr. Charles Baeder Williams, resident physician in the Pennsylvania Hospital for the Insane, Philadelphia, a graduate of the Medical Department of the University of Pennsylvania in the class of 1889, died on January 9 at the age of 45 years.

Dr. Eugene P. Hickok of Brooklyn, N. Y., a graduate of the Long Island College Hospital in 1890, a member of the American Medical Association, the New York State and Kings County Medical Societies, and the Brooklyn Neurological, Pathological, and Medical Societies, physician to the Kings County Hospital, and associate physician to the Lutheran Hospital, died at Lake George on January 19, aged 51 years.

Dr. Joseph H. Willis died at Camden, N. J., on January 16 at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1880. Subsequently he served as resident physician in the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, and later in the same capacity in the Pennsylvania Hospital. He was a member of the Camden County Medical Society, of the Cam-

den City Medical Society, and of the New Jersey State Medical Society, a member and founder of the Camden County Society for the Prevention of Cruelty to Children. He was also a member of the State Board of Health.

Dr. Robert Franklin Winston of Thayer, Mo., a graduate of the Memphis Hospital Medical College in 1890, died at his home, on December 11, 1910, aged 46 years.

Dr. Osmon Royal of Portland, Ore., a graduate of the Boston University School of Medicine, Mass., in 1885, died suddenly while attending a football game, on December 31, aged 54 years.

Dr. Reuben Harmon of Onawa, Iowa, a graduate of the Western Reserve University Department of Medicine in 1882, and a member of the Iowa State and Monona County Medical Societies, died on January 3, at Denver, Col., aged 59 years.

Dr. Robert J. R. Tilton of Carlisle, Ky., a member of the American Medical Association and of the Kentucky State and Carlisle County Medical Societies, died at his home after a long illness, on January 6, aged 79 years.

Dr. David R. B. Greenlee of Mayflower, Ark., a graduate of the University of Pennsylvania Medical Department in 1852, and a member of the Arkansas State and Faulkner County Medical Societies, died recently, aged 81 years.

Medical Director William Grier, United States Navy, a veteran of the Mexican and the Civil Wars, died at his home in Washington, on January 11, aged 94 years. He was appointed to the naval service from Maryland on March 7, 1838.

Dr. Frank Guy Sherwood of Albion, N. Y., a graduate of the Medical Department of the University of Buffalo in 1877, died at his home of pleuropneumonia, on January 26, aged 60 years.

Dr. Albert Joseph Mayer of New Orleans, La., a graduate of the Medical Department of Tulane University, New Orleans, in 1902, a member of the American Medical Association and of the Louisiana State and Orleans County Medical Societies, and surgeon in charge of the outdoor surgical division of Touro Infirmary, died at his home, on January 14, aged 33 years.

Dr. William H. Ramsey of Omaha, Neb., a graduate of the Beaumont Hospital Medical College of St. Louis in 1897, a member of the Nebraska State and Douglas County Medical Societies, and contract army surgeon of the Department of the Missouri, died suddenly on January 14.

Dr. Justin W. Lamson of Neosho, Mo., a graduate of the Rush Medical College, Chicago, in 1867, a member of the Missouri State and Newton County Medical Societies, and until the first of the year Superintendent of the State Insane Asylum at Nevada, died at his home, on January 16, aged 67 years.

Dr. Edmond Robillard of Montreal, Quebec, a graduate of the University of Bishop College, Faculty of Medicine, Montreal, in 1875, formerly governor and examiner of the College of Physicians and Surgeons of Canada, and secretary and treasurer of the Medical Association of the Dominion, died at his home on January 13.

Dr. George A. Binder of St. Paul, Minn., a graduate of the College of Medicine and Surgery of the University of Minnesota in 1865, a member of the American Medical Association and of the Minnesota State and Ramsey County Medical Societies, died at his home of typhoid fever, on January 15, aged 46 years.

Dr. Harvey L. Rosenberry of Wausau, Wis., a graduate of the Starling Medical College of Columbus, Ohio, in 1883, a member of the American Medical Association and of the Wisconsin State and Marathon County Medical Societies, and physician to the Marathon County Asylum for the Chronic Insane, died of apoplexy, on January 12, aged 53 years.

Dr. Benoni O. Reynolds of Lake Geneva, Wis., a graduate of the Rush Medical College of Chicago in 1851, a member of the Wisconsin State and Walworth County Medical Societies, and the oldest practising physician in the State, died at his home, on January 20, aged 87 years. He was at one time a member of the State Legislature and later of the State Board of Health.

Dr. Robert Swayne Prentiss of New York, a graduate of the College of Physicians and Surgeons, New York, in 1870, and a member of the Greater New York Medical Society, died at his home of angina pectoris, on January 28, aged 71 years.

Dr. Walter H. Snow of New Lebanon, N. Y., a graduate of the Medical Department of New York University in 1880, died at his home, on January 27, aged 51 years.

Dr. Stephen Taber Birdsall of Glens Falls, N. Y., a graduate of the New York Homeopathic Medical College in 1868, a member of the American Institute of Homeopathy and of the New York State Homeopathic Society, and physician to Parks Hospital, died at his home, on January 27, aged 66 years.

Dr. Charles G. Polk, who practised his profession for many years in the city of Philadelphia, died at Merchantville, N. J., on January 24. He was a son of a former Governor of Delaware and he was graduated from the University of New York in the class of 1858. He served during the Civil War on the staff of the Surgeon-General of the Army.

Dr. Donald Boyd of Valatie, N. Y., a graduate of the Albany Medical College in 1903, died suddenly, on January 23, aged 32 years.

Dr. Charles Lewis Morehouse of New York, a graduate of the Eclectic Medical College of New York in 1881, died at his home of pneumonia, on January 23, aged 88 years.

Dr. Joseph F. Somerhof of Newark, N. J., a graduate of the Bellevue Hospital Medical College in 1894, formerly professor of hygiene in the New Jersey College of Pharmacy, died on January 25, after a long illness, aged 44 years.

Dr. Martin P. Crawford of Lancaster, S. C., a graduate of the Medical Department of New York University in 1881, died after a long illness, on January 11, aged 53 years.

Correspondence.

HOLMES AND SEMMELWEISS.

To the Editor of the Medical Record:

Sir:—In a graceful tribute to Oliver Wendell Holmes, published in the latest issue of the Medical Record, the following statement occurs: "Holmes was probably not aware of what Semmelweiss was doing at the same time, another illustration of that noteworthy fact that many identical epochmaking ideas will appear at the same time in the minds of different men." That this is a serious historical error is evident from the recorded data in the "Geschichte der Geburtshilfe" von Siebold und

Dorn, 1903, which states on page 224: "On the 15th of February, 1843, *one year before Semmelweis graduated and four years before he introduced the cleansing of the hands with chloride of lime in the Vienna Maternity Hospital* (italics mine), Oliver Wendell Holmes read before the Boston Society for Medical Improvement an essay on the transmissibility of puerperal fever." And on page 226 appears the following: "Correct views of the causes of the diseases were universally current in America before the appearance of the monograph and letters of Semmelweiss."

In an address before the Historical Section of the Congress für Naturforscher und Aertzte in Carlsbad, 1902 (one year *before* Siebold's History appeared), I claimed for our countryman the priority over Semmelweiss, despite the fact that a monument had been erected in Budapest to perpetuate the latter's "discovery." To my great surprise no protest was made in this assemblage of Professors of History of Medicine. After the meeting, however, two Dozenten in this branch, one of whom is now Professor Neuburger of Vienna, whose excellent book was reviewed in a recent issue of the MEDICAL RECORD, requested the loan of my essay for "confirmation of data." It was returned to me with thanks. A few months later a weak polemic attack on my claim appeared in *Janos*, a journal of medical history, by Dozent von Györy, a countryman of Semmelweiss. The latter made a fatal admission by quoting from Semmelweiss' "Die Aetiologie, der Begriff und die Prophylaxis des Kindbettfiebers," Pest 1861, Seite 146, "The English never visit a healthy pregnant or parturient woman without previously washing their hands with chloride of lime." How long Semmelweiss had known this practice when he introduced it into the Vienna Maternity, is not recorded. It *is* recorded, however, that Holmes applied disinfection in 1843 (eighteen years before Semmelweiss' first personal claim), according to von Györy in *Janos*, 1902. It is also recorded that a friend whom Holmes quotes in his paper had not lost a case of puerperal fever since 1835 (twenty-six years before Semmelweiss' book) when he began washing with chloride of lime. Copeland, Ramsbotham, and others in England extolled Holmes' discovery, and the Registrar of England published an abstract of his essay. Therefore Holmes was probably the originator of the English practice of washing with chloride of lime to which Semmelweiss referred.

These exact historical data prove that the "discovery" of Semmelweiss was not coeval with that of Holmes. The first mention of the former was made in Hebra's Journal in 1848, *as a news item* and not by Semmelweiss himself. In this article the "contagiousness of puerperal fever was held by Semmelweiss as probable," while five years previously Holmes stated it as *positive*, and he wrote when assailed by ridicule of the eminent professors of midwifery, "The pestilence carrier of the lying-in chamber must look to God for pardon for man will not forgive him."

In the Carlsbad address I said "when it is remembered that his (Semmelweiss') mind was wrecked by the criticisms he encountered, even the most truth-loving historian must pause ere he would snatch one leaf from the laurel-crowned brow of this self-sacrificing man. Nevertheless historical justice demands that the claims of an American physician be recognized, etc." The published data establish the priority of Holmes (by five years) in the theory of transmissibility of puerperal fever and its prevention by disinfection. For Semmelweiss may be claiming priority in the use of the nailbrush which now plays so important a rôle in asepsis. Fiat justitia, ruat cœlum.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEDICAL TREATMENT OF SCHOOL CHILDREN—ULTRA-CHRONIC DISEASE—BERIBERI—INFLUENCE OF PARENTAL ALCOHOLISM ON OFFSPRING—HOMEOPATHY—MEDICINE "THROUGHOUT THE UNIVERSE"—OBITUARY.

LONDON, January 3, 1911.

THE medical treatment of school children is acquiring more interest outside professional circles. This week the subject was discussed at a conference of charity organization societies, where it was urged that care committees should be attached to the schools who should fit themselves to visit the homes of the children, teach the parents the importance of obedience to the doctor, the danger of unhygienic conditions, and so on.

Miss Matheson advocated such voluntary committees, and other attempts at improvement, in a paper quoting returns by medical officers which revealed a terrible amount of disease and inefficiency which might have been prevented by early parental care and elementary knowledge of hygiene. She estimated that above a third of the present generation of school children stood in need of some medical treatment, and that the Board of Education had only so far played a waiting game. The first step was naturally to secure the cooperation of parents, and for this reason it was usual to invite them to be present at the medical inspection. In Middlesex about 90 per cent. accepted. If committees were started independently of the educational authority they must do their utmost to secure cooperation with the official staff, must be pioneers where a slow council was in power, though in the opposite condition, if a progressive board, they might have hard work to keep abreast with it.

Mr. Griswood supported voluntary committees, as it was certain that ignorant or careless parents could not be trusted to carry out the doctors' directions. In Liverpool, he told the meeting, the education committee were ready to pay any cost which was proved to be justified; at the same time, unless parental responsibility could be brought home, they were only heating the air in this and other departments.

The Rev. F. J. Key said his experience in West Ham in following up cases did not impress him with the success of voluntary workers. On the other hand, teachers and attendance officers had rendered great assistance. As the result of their instructions some of the children became hygienic missionaries, and on visiting some poor home where windows were open which used to be hermetically sealed the mother would explain "My little girl says we must have fresh air. They teaches that at school."

Mr. C. Jackson, ex-chairman of the London County Council Committee, keenly believed in voluntary work as better than official or paid, however sympathetically it was done. A resolution was adopted in favor of voluntary committees, after which Mr. Motion read a paper in which he explained the measures adopted at Glasgow for putting down

baby farming, which he reported was now practically extinct in that city.

Another resolution recommended cooperation between boards of guardians and education authorities for dealing with neglect and destitution among children, and pointing out the facilities afforded by the city for doing so.

Ultra-chronic is a term which may fit cases of disease which are prolonged to a period far beyond that assigned to them in textbook prognosis. Dr. Batty Shaw employed it in an interesting lecture last month at the Brompton Hospital, to which he is an assistant physician. He was speaking of cases of pulmonary tuberculosis which extend over long periods, and which he has traced from their appearance under him to former admissions to the hospital under his predecessor. He has been able in a considerable number to look back to former periods of illness, after which they disappeared, perhaps for years, and then returned. Some left and returned more than once. In one case he obtained a history going back for thirty-nine years, but in this the diagnosis was first made ten or eleven years before Koch's discovery. In later cases he has selected those in which the tubercle bacillus was found in the expectoration by one of his predecessors. Dating from the first time the organism is detected is certainly the best way of fixing the period during which no doubt could exist as to the diagnosis. On the other hand, many cases of consumption which have been called prolonged, and others thought to have been arrested for various periods, will be remembered by men who have had large opportunities in private practice—and these, too, cases in which no doubt has been experienced by skilled observers. Dr. Shaw tabulated two hundred and twelve cases, lasting five years and over—patients who had only the assistance of outdoor hospital treatment. It is to be added that the length of time shown in these cases (one of which, as stated above, extended to thirty-nine years) does not express the duration of life from the onset to death. But the cases together show that pulmonary tuberculosis does not necessarily reach a fatal end in the two to four years so often assigned as a prognosis. In the cases mentioned, however, there is a great falling off of the survivors after fifteen years. The total of such survivals is fifty-three, representing about one-thirtieth of the total number examined by Dr. Shaw. These fifty-three may certainly be considered as those most likely to prove amenable to hygienic and therapeutic measures, and yet Dr. Shaw said all but eight of them followed indoor occupations. He suggested that possibly we might have less fear of those who have had hospital or sanatorium treatment returning to their previous work, even though it be indoors.

Staff Surgeon A. P. Laurie, from a study of an outbreak of beriberi on H. M. S. *Spitfire*, thinks that the symptoms resemble those of copper poisoning, and he found that the cooking utensils were made of this metal, the interior being tinned, but in many of them the tinning was worn off. Other circumstances confirmed his opinion, and these he has stated in a communication which is printed in the appendix to navy report. He says in India the natives neglect the retinning, and often suffer from gastric and intestinal symptoms as a consequence. Their food, too, is likely to take up copper, being fatty and often rancid. In copper poisoning, as well as in beriberi, neuritis is common, and similarly cardiac symptoms may be due to the same cause. He tested pus from the ulcerated gums in one case, but the reaction was not distinct enough to satisfy him that it was due to copper.

Dr. T. B. Hyslop gave his presidential address to the society for the study of inebriety on Tuesday. He took for his subject the "Influence of Parental Alcoholism on the Physique and Ability of Offspring." He said there was some evidence, supported, too, by experiments on animals, that alcoholism tended to increase the number of births, but to render the offspring weaker. Epilepsy, mental weakness, insanity, deaf-mutism, stunted growth, and other states transmitted by heredity, were apt to be not only intensified, but made their appearance at an earlier age when parental alcoholism was a factor. It accentuated the downward trend of psychoneurosis, and with each successive generation the offspring became alcoholic or degenerate at relatively earlier ages. Thus alcohol as an additional factor to parental degeneracy aided in the revolution of the stock. The conclusions of the Galton Laboratory and School of Eugenics, like their critics, dealt only with part of the question. When further investigations had demonstrated the combined influences on the physique and ability of offspring we might better be able to speak authoritatively for the guidance of the community. On families prone to degeneracy alcohol appeared to the lecturer to put the finishing touch, and render the offspring more unsatisfactory. It set alight the existence of neuroses and pychoses which might be on the wane, and rendered the offspring more liable to the transmission of the degeneracy not only in parental intensity but in manifestation at an earlier age.

Among letters of regret for absence one was from Professor Karl Pearson, who wrote that the society did not seem to him to be occupied with scientific study of any kind.

Sir V. Horsley said there were two points to consider—parental alcoholism, *per se*, and heredity of psychoneuroses. With the latter the Galton Laboratory had nothing to do. They professed that a drunken workman was as good as a sober one, and that his children were, if anything, rather better in physique and ability than those of persons who did not drink. Dr. Mary Sturge and himself were publishing a detailed criticism showing that Miss Elderton and Professor Pearson only reached their startling conclusions by disregarding facts, and that they had published imaginary statistical data where none existed. Consequently, they arrived at the erroneous conclusion that drunkenness was no sociological evil to the individual or to his offspring.

Dr. Salceby said there was need for further inquiry, and he advocated experiments on animals.

The recent death of a successful homeopathic physician has given rise to a good deal of gossip as to the attitude of the profession toward the holders of the exclusive dogma laid down by Hahnemann. Dr. R. Farquharson, a quondam teacher of therapeutics, has suggested that we might at this time reconsider our attitude toward the professors of that dogma, who he says can treat disease on a "much more scientific principle" than we possess, but what that principle may be he does not specify. He declares, however, that the "absurd doctrines of Hahnemann have long since been abandoned." If so the professors of these "absurd doctrines" need feel no difficulty in disclaiming them, and abandoning the position of separatists. Dr. Farquharson's good nature may prompt him to speak kindly of those who hold themselves out to the public as the

only persons who possess therapeutic truth, but surely his sense of logic must be acute enough to show him that the assumption of an infallible rule, unless he approves it, must render consultation or cooperation futile, if not deceptive.

One of our journals, which may well claim the first place, advertises that in it "the medical profession in all parts of the world will find the best means of keeping themselves informed of the progress of medicine and surgery, and kindred subjects, throughout the universe."

Dr. Edgar Jones, supposed to be the oldest living doctor, celebrated his one hundred and first birthday last week. He has been a magistrate for Essex for nearly sixty years.

Dr. Ebenezer Davies, who was medical health officer for Swansea for forty-three years, died there on Monday, aged eighty. During his long term of office the population of Swansea increased from 45,000 to 102,000, the mortality rate, nevertheless, falling from 28 to 18 per 1,000. That he was a devoted medical health officer may be judged by his remarkable record. He was also deeply interested in philanthropic and religious work. He published "A Retrospect," which was his address as president of the South Wales Medical Health Officers' Society, 1904.

Dr. John Coombe Maddever of Walsall died suddenly on the 9th inst., aged sixty-one. He was medical health officer of the Brownhills District, surgeon to the Hammerwich Hospital, and several collieries. He took M.D., Glasgow, in 1874.

Dr. Harriett Amelia R. Apps has died at Nablus, Palestine, where she was medical officer to the Missionary Society's Hospital. She was M.B., B.S., Durham, 1909, aged thirty-one.

Captain Chas. Hy. Johnson, who served as staff surgeon to the Turkish contingent in the Crimea, and was awarded the order of the Medjidieh, and was also given a commission in the Turkish army, died on the 7th inst., at an advanced age. He was only twenty-two on being appointed to the Crimea. On returning he practised in Shropshire and in London. Later he became medical health officer for Basingstoke. He retired in 1897.

From Durban comes the announcement of the death of Dr. Frank R. H. Potts, district surgeon and health officer at Stanger, who had served as civil surgeon attached to the R. A. M. C. in South Africa in 1900-01. His death occurred after an operation for appendicitis, at the age of forty-seven.

The Sanatorium Treatment of Neurasthenia and the Need of a Colony Sanatorium for the Nervous Poor. F. K. Hallock.
Alimentary Gastric Hypersecretion and Gastric Atony. A. E. Austin.
The Functional Spine. J. D. Adams.
Institutional Forms of Manic-Depressive Insanity. I. H. Neff.
Common Salt and Fluid Retention—A Clinical Example. E. D. Bond.

Sanatorium Treatment of Neurasthenia.—F. K. Hallock advocates the establishment by the State of a colony sanatorium for the treatment of functional nervous diseases, for the following reasons: First, the number of patients needing treatment is great; hence there is a demand. Second, there are no suitable institutions or places of treatment for these patients. Third, such an institution would prevent more serious illnesses. (1) Many cases of ordinary nervousness, impending neurasthenia, hysteria, etc., would undoubtedly be aborted by suitable treatment and removal from the aggravating home environment. (2) It is certain also that some cases of impending psychosis would be checked. To accomplish such results as these would alone justify the founding of the institution. Fourth, such an institution would effect more rapid cures than could be obtained under any other kind or form of treatment. Fifth, a certain proportion, and a not inconsiderable one, of chronic cases hopelessly drifting along as burdens to themselves and families could be cured by proper sanatorium treatment. The saving of such patients from the fate of becoming physician and dispensary "rounders," or surrendering themselves abjectly to chronic invalid habits would have a very positive economic value, to say nothing of the great relief of both individual and family suffering. Sixth, the more rapid relief and cure in acute cases would lessen the period of disability. This would mean an economic saving, both direct and indirect, in very many families throughout the State. The value of the earlier return to work, either as the wage-earner or, as the woman, head of the family and home, cannot be estimated, but it certainly must be great.

Gastric Hypersecretion and Atony.—A. E. Austin states that in alimentary hypersecretion, on account of the irritation produced by food, the meals should be limited to three daily, and effort should be made, by the use of belladonna preparations, to limit the amount of secretion; in case of atony, however, the meals should be more numerous, at least five, on account of the lack of motility of the stomach to empty itself, and recourse should be had to nux vomica and the strychnia preparations.

The Functional Spine.—J. D. Adams concludes that in treatment there is nothing new offered, but results show that there is a certain class of occupation spines which, through vocation, present a functional disability, and if there are no facts to sustain an organic or bony change, one is not justified in splinting the back to the extreme detriment of its future capacity. There may be present the classical symptoms of muscular spasm, limitation of motion with affection of either nerve, muscular, or bony origin. With a muscular strain the spasm present is more or less of a voluntary nature and may be largely eliminated by tolerance of pain in motion, whereas should the affection be of bony origin, the patient has no control over the muscular spasm. It has been the author's experience to see far too many cases tied up in rigid apparatus, with its untoward effects, where results have shown that they would have been far better to have supplemented a light support with counter-irritation. The support consists of a belt, reinforced with light steel, and, should apparatus be needed for muscular support, in this are incorporated all the necessary qualifications devoid of appreciable weight, and allowing enough freedom of movement to be consistent with comfort and efficiency. Its advantages over simple strapping are that it encases the body in such a way as to act as a purse string, thereby producing equal pressure and fixing the muscles much more efficiently than when we attach adhesive plaster to two sides of the pelvis, which are both movable. The best form of counter-irritation is that obtained by the use of dry heat. The apparatus for baking is constructed as follows: A small wooden box 18 by 20, the top being left open, lined with asbestos to prevent radiation, is fitted up with six sixteen-candle-power electric lights. The sides are curved to fit the outline of the back. The box is then placed on an upright on the wall and rendered adjustable to any height by a movable peg in a series of holes in the upright. The patient is then placed on a stool and the heat applied to the area to be treated. The heat is applied to the bare skin, temperature of 300°, for a period of fifteen minutes. The result shows a marked hyperemia with excessive perspiration, and with relief from pain.

Manic-Depressive Insanity.—I. H. Neff states that cases of manic-depressive insanity, mild in type, but with a characteristic and classical syndrome, are often unrecognized. It is obvious that if such a condition were detected in its incipiency improvement might result from treatment, and the degree of responsibility of these cases might be more accurately determined. Physicians who have observed and studied such cases, will, it is thought by the author, recognize that the symptomatology corresponds quite closely to that described as "hypomania," and will bear him out in the statement that it is often extremely difficult to secure the commitment of these cases to a hospital for the insane, as the patient's proper mental status is not understood by the average jury of laymen.

Common Salt and Edema.—E. D. Bond reports a case showing the influence of common salt in the causation of edema.

Metastasis to the Nervous System from Cancer of the Stomach and Intestines. H. L. Elsner.
The Organic Basis of Neurasthenia. J. M. Swan and C. C. Sutter.
Do Medical Schools Adequately Train Students for the Prevention of Infant Mortality? I. S. Wile.
The Significance of the Bacillus Carrier in the Spread of Asiatic Cholera. A. J. McLaughlin.
Asthma and Anaphylaxis. J. H. Barach.
Some Clinical Methods of Diagnosis of the Functional Activity of the Heart. J. Schneyer.
Indications and Directions for the Use of Albumin Milk. I. A. Abt.
Some Phases of Asthenopia—A Study of Eye Strain. D. W. Hunter.
A Rapidly Fatal Case of Amebiasis, with Abscess of the Liver, Originating in the Village of Green Island, New York. J. B. Harvie and H. W. Carey.

Metastasis of Cancer to Nervous System.—H. L. Elsner states that cases of stomach cancer without symptoms in which metastasis to the nervous system present may exist, in which, as in dogs after gastrectomy, the intestinal tract soon learns to compensate for the loss of the stomach function. But a slight acquaintance with the facts of clinical medicine are sufficient to prove that metastasis to liver, lung, and to other organs, including the nervous system, may occur, although the most painstaking examination fails to give any knowledge of the site, or even the existence of a primary malignant process. In these cases the secondary growths are often conspicuous. Symptoms of disease of any part of the nervous system in the presence of visceral disturbances should be regarded with suspicion. It is a grave mistake to dismiss with a diagnosis of "hysteria," "neuralgia," or "functional disturbance" the obstinate, agonizing, and recurring pain, radiating along the spinal nerves, because of their freedom from association with objective signs of organic disease. The symptoms in these cases may be "distant, irregular, remote in time and situation, and wanting in precision." The study of the symptoms of metastasis to the bone of the skull or to the brain include the usual stomach symptoms, anemia, with the loss of weight; the severe headache of brain tumor, disturbance of vision and locomotion, double optic neuritis, with irregular, staggering gait, while there may be focal symptoms as with primary growths, depending upon the location of the deposit. In those cases of brain invasion seen by the author, associated with spinal invasion or peripheral neuritis, or with both, the symptoms of the early metastasis have been augmented by the addition of those of the cerebral complication, and the presence of the latter has been early suspected, and, as a rule, promptly diagnosticated. Finally it is mentioned that occasionally the diagnosis of cancer of the stomach with metastasis to the nervous system has been made by the unguarded in cases of pernicious anemia with atrophy of the gastric follicles and prominent "Lichtheim symptoms," including the usual altered gait, anesthesias, and paresthesias. No differentiation in the whole field of medicine is more simple. The author's entire experience offers no case of pernicious anemia in which the sensory symptoms have in any way resembled those associated with metastasis due to visceral cancer. In none have there been agonizing pains. No case of cancer with metastasis to the nervous system has been seen in which the fat bolster has been retained and in which cachexia has been absent, none in which the blood picture failed to clear the horizon.

Organic Basis of Neurasthenia.—J. M. Swan and C. C. Sutter cite nineteen cases due to cardiovascular disease; four myocarditis with low blood pressure; one myocarditis with arteriosclerosis; ten arteriosclerosis with high blood pressure; four beginning interstitial nephritis; three case due to pulmonary disease; nine cases due to gastrointestinal disease; three cholecystitis, one appendicitis, four very marked constipation, one pyorrhea alveolaris; four cases were postoperative; one case was due to scoliosis; one case was due to syphilis; four cases were due to overwork; three cases were due to nervous shock; seven cases were undetermined. Of the total of fifty-one, thirty-seven were dependent upon organic disease, 72.5 per cent.; fourteen cases were apparently independent of organic disease, 27.45 per cent. In conclusion, the author emphasizes the necessity for adopting the well-tried methods of examination that serve so well in plainly developed chronic disease as a routine measure in neurasthenics. Many times one will discover underlying organic changes responsible for the disturbance in the nervous equilibrium. The relief of the former ought to be followed by relief of the latter. Such cases should not be called neurasthenic.

Prevention of Infant Mortality.—I. S. Wile states that obstetrics, pediatrics, and hygiene should be taught in the light of the social basis of disease. At the present time medical schools do not prepare students for the work of preventing infant mortality. If physicians are to be leaders in the preventive medical work that is now the present ideal in medicine, the medical schools must awaken to their responsibility and duty in the matter of affording the adequate training to the students who go to them for the purpose of being trained in all that makes for the highest type of efficient, conscientious, humanitarian physician. In short, preventive pediatrics must be taught. This becomes possible only when it is a required course, based upon the present day needs of the community. To be successful the preventive work in pediatrics must have a foundation in the knowledge that the faulty social structure is at the basis of many of the ills that infant flesh has thrust upon it.

The Bacillus Carrier in the Spread of Cholera.—A. J. McLaughlin found that the percentage of carriers of the cholera vibrio among healthy individuals was 6.44. An outbreak of cholera was quickly suppressed in Bilibid prison following an order by the writer to compel thorough disinfection of the hands under guard upon leaving the latrines and before eating. To prevent recurrence disinfection and screening of the latrines, sterilization of water, prohibition of uncooked food, vegetables or fruits, prohibition of the use of fresh milk, hand disinfection before leaving latrines and before eating, five days' quarantine of incoming prisoners, and stool examination for cholera of incoming prisoners were enforced. In spite of the presence of cholera in the surrounding provinces, these measures sufficed to prevent recurrence.

Asthma and Anaphylaxis.—J. H. Barach states that the results of his investigations regarding the relation of asthma to anaphylaxis are to be considered negative. If anaphylactin was present in the blood of the asthmatic it could not be demonstrated with the given technique by this method. This one negative result is to be considered, however, as a mere incident in a big and important problem.

Functional Activity of the Heart.—J. Schneyer reviews the various methods of testing the functional activity of the heart. 1. Change of pulse rate on change of posture of the body. A number of investigators detected that in healthy individuals, on changing from the upright to the recumbent posture of the body, the pulse becomes slower by a few beats. In various diseases the heart does not respond by the usual slowing of the pulse on change of posture of the body from the vertical to the horizontal. The absence of normal reaction of the pulse on change of posture of the body may occur in various cardiac disorders, as well as in other acute or chronic diseases, and indicates functional incompetency or insufficiency of the heart. In patients having anatomical lesions of the heart, but with good compensation, the change of the pulse rate on change of posture of the body is normal. 2. Estimation of cardiac function by pressure on the femoral arteries. Physiologists have long observed that pressure on a large vessel in healthy animals produces a slowing in the rhythm of the heart and a rise of blood pressure. Shapiro, in 1881, concluded that pressure exerted on the femoral arteries in individuals suffering from cardiac weakness would cause the heart to react entirely differently than in health. He reported eleven cases of heart disease in which it is distinctly shown that in case of ruptured compensation, pressure on the femoral arteries would cause an increased frequency of the pulse, and when compensation was reestablished, the physiological reaction of slowing of the pulse rate returned. The same reaction was noticed in individuals suffering from other diseases and presenting cardiac insufficiency. Katzenstein improved upon Shapiro's observations. He added the theory of blood pressure; a rise of pressure in health and a fall of the same in cardiac insufficiency of a severe type, no change in blood pressure in milder types of incompetency of the heart. This method became known under the name of Katzenstein's method. 3. Muscular exercise as a means of estimating cardiac function: The heart reacts upon physical exercise in disease differently than in health. Work, therefore, is quite often used as a means of testing the functional aptitude of the heart. The patient is required to rise from bed, to walk rapidly to and fro, or to climb stairs, and is then examined as to the character of his pulse and heart sound, as to pallor, cyanosis, and dyspnea, vertigo, and other phenomena of cardiac insufficiency. The ergometer is an apparatus devised by Graupner for estimating the amount of work done by muscular action. The patient is asked to do some work on this apparatus, and then the time necessary for the heart to recuperate from the exertion is estimated, and also the blood pressure is taken. The patient is told to repeat the work, each time increasing the amount, and blood pressure and the time necessary for recuperation are estimated each time, until a fluctuation, or even some fall of blood pressure is noted. If upon repetition of the work the recuperation time becomes less and the blood pressure rises or remains unchanged, Graupner concludes that the heart is up to the given task. On the other hand, if the time required for the heart to recuperate lengthens and blood pressure decreases, the heart is not strong enough to perform the given work. Thus, he concludes, blood pressure on repeated muscular exertion rises in cases of health and falls in cardiac insufficiency.

The Use of Albumin Milk.—I. A. Abt discusses the indications and directions for the use of albumin milk. This prevents abnormal fermentation in the intestinal tract on account, first, of the low content of easily fermentable milk sugar; second, of the low content of whey salts (the latter favor fermentation); and, third, on account of the comparatively high proteid content (the latter counteracts fermentation). Upon standing, a precipitate is likely to form in the bottle containing the albumin milk. Before feeding, the bottle should be well shaken. The quantity to be fed should be warmed to the body temperature and again shaken. (Overheating is objectionable). The milk should be kept in a cool place. If thus taken care of, it preserves its quality well for at least five weeks. Albumin milk contains 3 per cent, proteid, 2.5 per cent. fat, from 1 to 1.5 per cent. of milk sugar, from 0.4 to 0.5 per cent. of mineral salts. The mixture contains 450 calories to each litre. In addition, 1 per cent. of malt sugar (Nähr Zucker) is added.

Phases of Asthenopia.—D. W. Hunter, in considering the causes of this condition, divides the cases into five classes: 1. Cases dependent on the general health. 2. Reflex cases. 3. Those due to errors of refraction and accommodation. 4. Muscle cases. 5. Mixed refraction and muscle cases. Prisms have the following therapeutic action: They may satisfactorily correct a real muscular insufficiency permanently. They may be of use temporarily by relieving muscles fatigued and strained by overwork, and then be laid aside when the muscle tone has been restored by rest or improvement of the general condition. They may correct an apparent error and develop a latent one. That is, a weak muscle gladly accepts the proffered help, relaxes its tension, and asks no more. They may, by exercising it, strengthen a weak muscle—prism gymnastics. They may be absolutely useless, and even harmful.

Amebiasis in New York.—J. B. Harvie and H. W. Carey report a rapidly fatal case of amebiasis with abscess of the liver, originating in the village of Green Island, New York. They are in accord with Patterson in the belief that amebic dysentery is endemic in New York State, and if a closer search is made for the nature of intestinal infections in general many additional cases will surely be found.

Journal of the American Medical Association.

January 21, 1911.

Report of Six Cases of Composite Odontomes. T. L. Gilmer.
Infections of the Endometrium. W. S. Gardner.
Perforation of Uterus and Transfixion of Contiguous Mesentery and Peritoneum by Bone Crochet Needle. E. G. Edwards.
A Chronic Itching Eruption of the Axillæ, Pubes and Breast. M. Haase.
Report of Seven Cases of Syphilis Treated with Salvarsan. M. Marshall.
An Interesting Case of Confusional Insanity. J. W. Meehan.
Foreign Material in the Stomach. A. H. Vandivert and H. P. Mills.
Diagnostic Value of Local Tuberculin Reactions. I. B. Sachs.
The Modern Treatment of Syphilis with Reference to the Recent Arsenic Preparations. J. A. Fordyce.
Treatment of the Pains of Acute Anterior Poliomyelitis. T. A. Williams.
Simple Complete Tonsillectomy. G. E. Gwinn.
A Case of Tabes Dorsalis without Ataxia. A. A. Eshner.
What Becomes of the Spirochetes in the Secretions? F. R. Charlton.
Two Appendices in One Person. W. G. Young.
Transmission of a Malignant New Growth by Means of a Cell-free Filtrate. P. Rous.
Pyelitis Gravidarum. T. J. Doederlein.
Abdominal Diphtheria. B. C. Everall.

Composite Odontomes.—T. L. Gilmer reports six cases of composite odontomes in the human subject which are of interest, first, on account of their rarity, and, second, on account of their being occasionally mistaken for malignant growths, with consequent removal of large sections of the jaw which could have been avoided had a correct diagnosis been made.

Infections of the Endometrium.—By W. S. Gardner. See MEDICAL RECORD, vol. 77, page 1031.

Perforation of Uterus.—E. G. Edwards reports a case of the passage of a bone crochet needle through the uterus and the adjacent mesentery and peritoneum without producing pain, shock, hemorrhage, or infection. The perforation of the uterus by instruments, even in skilled hands, is not a rare occurrence, but its perforation and the passage of the instrument through the uterus into the peritoneal cavity must certainly be. The case demonstrates the utility of the radiograph in clearing up what would have been, in the absence of subjective and ob-

jective symptoms, a puzzling case as to the proper method of procedure.

Lichen Dermatosis.—M. Haase refers to the lack of attention which has been given to a class of skin infections designated by Brocq under the term lichenification, cases of which have been reported by Fox and Fordyce in this country.

Salvarsan in Syphilis.—M. Marshall reports the rapid onset of improvement after the administration of this remedy, in six cases of syphilis.

Confusional Insanity.—J. W. Meehan reports a case of this condition, in which the mental symptoms followed an operation for appendicitis. Recovery was abrupt.

Foreign Material in the Stomach.—A. H. Vandivert and H. P. Mills report a case remarkable for the number and weight of the articles removed, as well as for the size and peculiar forms of some of them, especially so when considered in connection with the fact that there had never been any symptoms suggesting trouble with the stomach. The objects removed at autopsy consisted of 453 nails, 42 screws, 9 bolts, and 942 miscellaneous articles.

Local Tuberculin Reactions.—I. B. Sachs concludes that a large clinical experience substantiated by necropsies in a proportion of cases, points strongly to the efficiency of the local tuberculin reactions. The verdict today is that a positive reaction following local application of tuberculin (conjunctival or cutaneous) signifies the existence of a tuberculous focus in the organism without giving a definite idea as to its active or latent character. Reactions vary according to the site of the inoculations, and a clear description in each individual case should be given as to the locality used. This is necessary for the comparative study of the work of different observers. Tests of various dilutions of tuberculin contribute to the belief that the actual amount of absorbed tuberculin is an important factor in determining the degree of the reaction. The claim that a positive conjunctival reaction signifies active tuberculosis is not substantiated. It is possible, however, that the activity of a tuberculous process may, under certain conditions, be a factor in causing a positive local reaction with a minimal dose of tuberculin and further experience with the test, and various dilutions applied to various groups of cases with a perfected technique, assuring absorption of definite quantity, may possibly lead to some method of differentiation of active and latent cases. Patients with suspected tuberculosis with a rapidly developing and marked cutaneous reaction, generally respond readily to the subcutaneous injections of minimal doses of tuberculin. Hence the relative value of such cutaneous tests in cases in which the employment of the subcutaneous test is contraindicated. The subcutaneous test remains the decisive diagnostic procedure in doubtful cases of tuberculosis, particularly if a local reaction is desired. The possible unfavorable effects of this test in some cases may be avoided by the use of small doses of tuberculin (initial 1/5 or even 1/10 mg.), according to the age and condition of the patient. The use of these tests opens a new field for further clinical and laboratory research which may provide a safe, reliable method of diagnosing obscure and early cases of tuberculosis.

The Modern Treatment of Syphilis.—J. A. Fordyce states that the impression first given by the reports, that it was possible to eradicate the infection entirely by one dose of salvarsan, has been proved erroneous, as has also the opinion that a special susceptibility to the drug could be acquired. The remedy has been used in eighty-four cases so far in the New York City Hospital. The injections are painful, usually requiring morphine, but pain does not last over twelve hours in most cases. In a few cases there appears to be a special susceptibility to the drug, and the reaction is very severe. Its effect on primary lesions is very striking, but the most brilliant results altogether have been obtained in mucous membrane lesions, and almost as much with gummata. Bone lesions are quickly affected, but these often disappear quickly under mercury. Malignant syphilis with multiple bone lesions, resistant to mercury, were, however, markedly influenced by the arsenical treatment. The treatment in tabes has not been very encouraging, probably on account of the degenerative conditions which have been induced. There is a suspicion, based on certain reports of cases like one here given by the author, that the treatment may have disastrous effects on vision, though no degenerative changes have been found in experimental animals. Two striking cases of hereditary syphilis are briefly reported. Fordyce concludes from the study of his observations that salvarsan has not been found absolutely curative in a single dose, but that it is a most efficient agent in controlling the early symptoms and limiting the contagious stage. A therapeutic blow in the early stage, when the spirochetes are numerous, must have a marked effect on the later development, and the result of one injection is fully equal to that of a long course of mercury and mercury and iodide, without their unpleasant by-effects. The objections to the use of salvarsan are the pain it produces in its intramuscular injection, and the present uncertainty of its effects on the eyes. Administration by the intravenous method, however, obviates the first mentioned difficulty, although it requires more technical skill. He thinks it better for the present not to employ it as routine treatment, but to use it only in cases where it is specially indicated, carefully observing all the precautions laid down by Ehrlich. Every patient should be examined by an ophthalmologist before the drug is administered, and patients should have hospital care for four days or a week afterward. It would be better to lengthen the period of hospital observation rather than to shorten it.

Pains of Poliomyelitis.—T. A. Williams notes that pain has been a prominent feature in many recent cases of infantile paralysis, having been reported as marked in 50 per cent. of the cases analyzed by the New York Committee. His observations have shown that there are two distinct types of pain in the disease. The first is that due to meningitis, which he does not consider here. The second is analogous to the normal pain and tire resulting from cramped positions or prolonged exertion. It is due to stretching and sagging of muscles and joints. The best proof of its nature is found in the methods by which it can be relieved, which all depend on the relief of the causes above mentioned. The methods used are galvanic electricity, suspension, and support. Of these the first is the most efficacious, as it excites contractility as no other method does. While many textbooks and authorities advise the postponement of the use of electricity for two months in this disease, this, he says, is due to the misconception that it is an inflammatory disease of nerve and muscle when, in fact, the inflammation is confined to the cells of origin in the cord, and is essentially interstitial. His experience with galvanism in the first week of the disease is that it afforded great relief, enabling positions which were before intolerable to be maintained with ease, and facilitating the prevention of contractures. Another method is suspension in the bath, which exerts an even pressure, and its value is not exaggerated in the report of the New York Committee. The third method is suspension or support of the trunk and limb in slings or cradles, or by pads or tipping of the bed. Degeneration commences within three days, and is decided on the tenth day. While recovery is a matter of months, the importance of encouraging the patient to make voluntary efforts is evident. To overcome the tendency of the child not to do this, and to encourage him, the limb should be

placed in the best possible position to make a movement visible to himself. The best of all situations is suspension in water, and this is a second advantage of the use of the warm bath. It is also important to make movements interesting to him by games, etc., conformed to the special needs of the case. Psychological considerations are also important in the after care of a paralyzed patient. Contact with social environments must be fostered. Stories of others who have overcome physical difficulties are among the means mentioned, and the range of opportunity for a cripple in good health is not as limited as it might appear.

Simple Complete Tonsillectomy.—G. E. Gwinn describes the technique of his operation for complete removal of the faucial tonsil with its investing capsule.

Tabes without Ataxia.—A. A. Eshner reports a case which he regards as of interest because of a total absence of ataxia, although the disease of the spinal cord appeared to be at least of several years' duration.

Spirochetes in the Secretions.—F. R. Charlton propounds the query suggested by salvarsan and offered as a subject for investigation, namely: What becomes of the spirochetes on the free surfaces not reached by the remedy, or perhaps, it would be better to say, in the retained secretions and excretions? Varying with the different stages of the disease, a certain number of the spirochetes will be found throughout the mucous surfaces. This means the mouth, the gastrointestinal and rectal areas inclusive, and the Eustachian tubes. The vagina and endometrium must carry countless numbers. The seminal vesicles and prostatic follicles are to be borne in mind. Endothelial sacs such as the pericardium, the pleura, it is fair to assume, contain many of these wandering forms. The spirochete has been demonstrated repeatedly in most of these secretions or excretions.

Two Appendices in One Person.—W. G. Young reports a case in which there were two appendices containing pus: one was ruptured. One appendix measured 3 by ⅜ inches, the other one 3½ by ⅜ inches. Their bases were 1¼ inches apart, and each had a mesoappendix. Drainage was instituted, the patient placed in the Fowler position, and continuous rectal saline by the drop method was employed for five days. The patient made a slow recovery.

Tumor Transmission.—P. Rous describes the results of his investigations, in which he succeeded in transmitting a malignant new growth by means of a cell-free filtrate.

Pyelitis Gravidarum.—T. J. Doederlein reports a case of this condition, in which the gastrointestinal disturbances are unusually prominent. These symptoms are of etiological importance. A great many observers lay much stress on the mechanical state of affairs during pregnancy as a contributory factor, namely, pressure on the ureter, especially the right, by the head of the child. The fact is that in most cases on record, as also in the author's, the symptoms left the patient as the head descended and pressure was relieved. The terrific cough, lasting two and a half months in the former and one month in the last pregnancy, and quickly leaving the patient on delivery, possibly was due to colon bacillus infection of the respiratory tract. In most cases the right kidney was affected, which was explained by the fact that the uterus leans toward the right side, the sigmoid protects the left ureter, and the presentation is mostly occipito-left anterior. Whether the presentation in the author's case, occipito-right anterior, had anything to do with the left kidney being affected, he would not venture to say. The diagnosis is, of course, more difficult in dextrolateral pyelitis, the disease being very apt to be mistaken for appendicitis, gallstones or typhoid. The tenderness over the kidney and along the course of the ureter, especially the pelvic portion, felt through the vagina, and the urinary findings, especially presence of the colon bacillus, ought to be sufficient to clear up the diagnosis.

Abdominal Diphtheria.—B. C. Everall reports a case in which, following an apparently cured nasopharyngeal diphtheria, the patient passed a large amount of foul and bloody feces, containing a necrotic membrane three inches long, having the appearance of a cast of some part of the gastrointestinal tract below the pharynx. The patient made a slow recovery, developing an extensive paralysis, with a persistent high pulse rate and obstinate constipation.

The Treatment of Disseminate Sclerosis: a Suggestion. E. F. Buzzard.
Torsion of the Left Broad Ligament and Fallopian Tube in a Child. M. A. Cassidy.
Massive Infarction of the Renal Cortex. J. A. Torrens.

The Influence of Parental Alcoholism on the Offspring.—T. B. Hyslop essays an answer to the question: Does parental alcoholism (of a pernicious kind)—apart from parental degeneracy, which together with a tendency to alcoholism, is hereditable—influence the physique and ability of offspring? It is practically impossible to exclude side issues, variations in standards of health, alcoholism, and degeneracy from consideration, and we have as yet but imperfect conceptions as to what is meant by heredity. Hence one cannot obtain sufficiently accurate data for statistical purposes. The association—in contradistinction to causation—of alcoholism and degeneration in the parent is insufficiently understood, and the difficulty in distinguishing between cause and effect, both in the parent and offspring, is so great that the decision must be frequently mere guesswork. The present problem requires that parental alcoholism shall precede conception or the birth of the child; whereas, in the transmission of a psychoneurosis by direct inheritance, the parental alcoholic tendency may be latent, and not come into evidence until after the birth of the child. This necessitates complete differentiation between the two series. Alcoholism would appear to be responsible for a relatively greater number of births than would health or degeneracy without alcoholism, and there appears to be some evidence derived from experiments on animals treated by alcohol that their young, although in greater numbers, were much weaker. Epilepsy, some forms of insanity, defective inhibition and mental enfeeblement, deaf-mutism, and stunted growth, although instances of what has been aptly termed the "general controlling determinant," and transmitted by direct heredity, are apt to be not only intensified in the offspring, but they make their appearance at a relatively earlier age, when parental alcoholism has been an additional factor. Parental alcoholism does appear to accentuate the downward trend of inherited psychoneurosis, and with each successive generation the period of exemption from alcoholism and degeneracy becomes shortened, so that the offspring become alcoholic or degenerate at relatively earlier ages. Alcohol would in this way act as a complementary factor to parental degeneracy, and aid in the devolution of the stock. The inheritance of a psychoneurosis (which would tend to diminish in severity with each successive generation, and with the introduction of new correcting influences through marriage) becomes intensified and prolonged when alcoholism becomes a complicating factor. In this

way the psychoneurosis is kept alight through a greater number of generations.

Sepsis and Antisepsis in Medicine.—W. Hunter states that in his clinical experience septic infection is without exception the most prevalent infection operating in medicine, and a most important and prevalent cause and complication of many medical diseases. Its ill effects are widespread, and extend to all systems of the body. The relations between these effects and the sepsis that causes them are constantly overlooked, because the existence of the sepsis is itself overlooked. For the chief seat of that sepsis is the mouth, and the sepsis itself, when noted, is erroneously regarded as the result of various conditions of ill health with which it is associated—not, as it really is, an important cause or complication. So with this septic infection in medicine, the effects fall sometimes more on the tonsils, pharynx, or glands of the neck; sometimes more on the stomach, intestine, and colon; sometimes more on the blood, causing anemia, purpuras, chronic septicemias, obscure fever; sometimes more on the joints, causing so-called rheumatic trouble; sometimes more on the nervous system, or on the kidneys, and sometimes it falls in a fulminating way upon the blood as a whole, causing a general infection with streptococci with or without infective endocarditis. The worst cases of anemia, gastritis, colitis of all kinds and degrees, of obscure fever of unknown origin, or purpura, or nervous disturbances of all kinds ranging from mental depression up to actual lesions of the cord, of chronic rheumatic affections, of kidney disease, are those which owe their origin to, or are gravely complicated by, the oral sepsis produced in private patients by the gold traps of sepsis. Time and again the author has traced the very first onset of the whole trouble of which they complained to a period within a month or two of their insertion. The sepsis hereby produced is particularly severe and hurtful in its effects. For it is dammed up in the bone and in the periosteum, and cannot be got rid of by any antiseptic measures which the patient or the doctor can carry out. Moreover, it is painless, and its septic effects therefore go on steadily accumulating in intensity without drawing attention to their seat of origin. In observing the degree of sepsis in his hospital cases, the author is in the habit of dressing the septic wounds. The method is to swab the edges of the gums and teeth with cotton-wool and 1 in 60 carbolic in order to clean off pus and to enable him to see the character and extent of the underlying wounds. The wounds are thereby dressed at the same time that they are being examined, and all superficial sepsis is got rid of. This antiseptic dressing of the gums should be carried out daily so long as open wounds are present, by the nurse or by the patient himself, and it is astonishing how quickly the septic conditions of the gums are improved thereby, and how quickly the patient feels and shows by his appearance the benefit of this antisepsis.

Subtotal Hysterectomy.—A. H. G. Doran analyzes a series of 100 cases in which he has performed this operation for fibromyoma uteri. In 40 cases, or 40 per cent., both ovaries were removed, and the menopause was neither immediate nor complete in 4; in 3 out of the 4 the amputation was above the os internum. In 39 cases, or 39 per cent., one ovary was saved, and the menopause was neither immediate nor complete in 21; in 18 out of the 21 the amputation was above the os internum. In 21 cases, or 21 per cent., both ovaries were saved. The menopause was neither immediate nor complete in 8; in 7, possibly all, of the 8, the amputation was above the os internum.

Gangrene in Diphtheria.—A. S. Ransome and E. M. Corner report a case of diphtheria in a boy six years of age presenting the following unusual features: threatened cardiac failure, albuminuria, paralysis, gangrene of foot, amputation of leg, and recovery.

Removal of Uterus for Diseased Adnexa.—J. M. Munro Kerr, appreciating so fully the importance of conservative treatment of the organs we have to deal with, thinks we occasionally fall into the mistake of not being radical enough in our operative procedures in those cases of extreme disease where it is obvious that nothing can be done by conservative measures. One is especially inclined, he thinks, to leave the uterus behind in certain ovarian and grave tubal conditions when we would obtain much better results, both immediate and remote, if we removed the uterus along with the diseased adnexa. As far as one can judge at present, and the recent researches of Carmichael go to support this, the uterus is merely a bag for retaining the impregnated ovum. It contributes no internal secretion. Kerr directs attention to two diseases of the adnexa in which he believes it to be of the very greatest importance that the uterus should be removed along with the appendages. The two diseases are malignant disease of the ovary and pronounced pyosalpinx.

Duodenal Ulcer and Appendicular Disease.—H. J. Paterson states that most of the patients suffering from appendicular gastralgia are cured by appendicectomy, but in from 10 to 12 per cent. of the cases operation is not followed by complete relief. An ulcer may already exist, although it cannot be felt by an external examination of the duodenum. This possibility raises the question whether in these cases a gastrojejunostomy should be performed as well as appendicectomy. He is of the opinion that a gastrojejunostomy should not be performed unless there exists a definite ulcer which can be seen and felt. He admits that it is disappointing, both for the patient and for the surgeon, if appendicectomy fails to relieve the gastric symptoms and further surgical treatment is necessitated; nevertheless, a 10 per cent. chance of a second operation being necessary does not justify neglecting operation in 90 per cent. of the cases.

The Treatment of Disseminated Sclerosis.—E. F. Buzzard states that the resemblance between cerebrospinal syphilis and disseminated sclerosis has led him, during the last year or two, to suspect that the latter disease may be caused by some organism belonging to the same class as that of the treponema. The fact that this class of organism is best combated by mercury or arsenic induced him to commence the tedious experiment of treating a few selected cases of disseminated sclerosis by repeated courses, or nearly continuous administration, of arsenic, on the same principle as that which makes the repeated administration of mercury the only effective method of preventing attacks of cerebrospinal syphilis in syphilized persons.

Torsion of Broad Ligament and Fallopian Tubes.—M. A. Cassidy and L. E. C. Norbury report a case of this condition occurring in a girl eleven years of age. They have ventured to put this case on record on account of the extreme rarity of the condition found. Torsion of the pedicle of ovarian tumors in children is, of course, not uncommon; in fact, the ovarian tumors of childhood appear to be very liable to this accident. Damianos refers to 14 cases of torsion of the uterine adnexa in inguinal herniæ of young children, and Morrel reports a case of torsion of the left Fallopian tube in a woman, aged 32 years, without any concomitant strangulation of the ovary. Haultan has published a case of apparently chronic torsion of the Fallopian tube and broad ligament, with infarction of the ovary; the operation was performed on account of metrorrhagia of 18 months' duration, and there were no acute symptoms. The authors have been unable to find in the literature any instance of acute strangulation of a healthy and normally situated tube and ovary.

Massive Infarction of the Renal Cortex.—J. A. Torrens reports the case of a patient who was admitted to the hospital with the history that seven days previously she had had a miscarriage at the fourth month, followed immediately by complete suppression of urine and two days later by obstinate vomiting, which persisted throughout the illness. Twenty-four hours after admission the patient died somewhat suddenly after complaining that she felt sick and faint. In cases quoted by Herringham and by Bradford, as well as in the present one, the anuria dated from childbirth or miscarriage, but so far as the author has been able to ascertain, this is the first case in which the lesion has been shown to be directly attributable to thrombosis of the renal veins, though it has been demonstrated by physiological experiment that obstruction to the renal vein will produce a condition of typical infarction.

The Results of the Surgical Treatment of Displaced Semilunar Cartilages of the Knee. D'Arcy Power.
Conservative Surgery of the Nose. W. S. Low.
On the Connection of Enlarged Cervical Glands with Carious Teeth, Enlarged Tonsils, and Adenoids. H. Osborne.
Draughts and Colds. R. C. Macfie.
On Some of the Biological and Statistical Errors in the Work on Parental Alcoholism by Miss Elderton and Professor Karl Pearson. M. D. Sturge and Sir Victor Horsley.

Surgery of Displaced Semilunar Cartilages.—D'Arcy Power states that the lines of treatment appear, therefore, to be well defined in cases of internal derangement of the knee-joint due to injury of the semilunar cartilages. When the patient is seen directly after the injury every care should be taken to replace the injured cartilage in position by well considered manipulation. Rest in an extended position must then be insisted upon until the swelling has subsided and time has been given for repair, massage being employed during the whole of this period. It must be borne in mind that no satisfactory result will be obtained if the injury be treated simply as a sprain by rest and cooling lotions. It is essential that the cartilage should be replaced, for otherwise it is as useless to rest the joint as it would be to rest an unreduced dislocation. When these methods have failed, or when the original condition has been badly treated, and the patient is left with a chronically inflamed joint, which is insecure, painful, and locking, the sooner an arthrotomy is performed and the interarticular cartilage is removed the better it will be for the patient. As might have been expected *a priori*, the author's inquiries show that the least satisfactory results are obtained when the patient has been allowed to go about with a damaged fibrocartilage for months or years, the best results when he has had only a few attacks of painful fixation of a joint. In these latter cases the ligaments have not become stretched, and the joint quickly resumes all its normal functions.

Conservative Surgery of the Nose.—W. S. Low states that the real test of successful surgical operative interference in the nose is, without doubt, to be ascertained by the answer to the question, how does the patient feel as regards freedom of respiration through and comfort in the nasal interior and pharynx six months afterwards? The most beneficent surgery is the most conservative as regards the preservation of the mucous lining, and is almost always attained by operating successively in stages, rather by what one might call physiological, than by severe, sweeping, sacrificial surgery.

Enlarged Cervical Glands and Carious Teeth.—H. Osborne states that his investigation presumes to supply a certain amount of statistical evidence as to the relation existing between enlarged lymphatic glands in the neck on the one hand and carious teeth, enlarged tonsils, and adenoids on the other hand. The numbers dealt with are comparatively small, and the results correspondingly liable to error. On the evidence of these tables it would appear that the presence of decayed teeth, enlarged tonsils, and adenoids are all associated with an increase in the percentage of children with enlarged glands, but, at the same time, this increase would appear to be much more pronounced in the case of tonsils and adenoids, and comparatively little in the case of carious teeth. Granted that the presence of either enlarged tonsils or adenoids is associated with enlargement of glands in the neck, one has still to consider whether such association is due to a general lymphatic hyperplasia involving both glands and other lymphoid structure, such as tonsils, or whether it is rather the catarrhal conditions to which tonsils and adenoids predispose that give rise to glandular enlargement. There is a third possibility—namely, that infecting organisms may obtain access more readily by way of enlarged tonsils and adenoids than through the healthy throat and nose.

Draughts and Cold.—R. C. Macfie comes to the conclusion that draughts do occasionally play an auxiliary part in the production of colds, but that they are easily deprived of their dangers, and should be favored rather than feared. To endeavor to escape colds by avoiding all draughts must always be futile and foolish policy, and will not only defeat its own aim by fostering bacteria and by promoting vasomotor lethargy and incompetence, but will lead to deficient vigor through interference with skin reflexes, which play an important part in the respiratory and circulatory functions. When we wish to excite the respiratory center of the newborn babe we appeal to its skin reflexes, and in cases of night sweats a breeze on the skin seems to give tone to the whole vasomotor system. The skin is certainly meant to be exposed to moving air currents and to vicissitudes of heat and cold; it is surely meant to have a blood supply that ebbs and flows according to the thermal needs of the tissues; it is surely meant to perspire and to transpire, and accordingly to shut it off from wind currents and to enclose it in a motionless layer of moist air is to depart very far from the ways of physiological righteousness. The bracing effects of dry air and of seaside breezes are largely due to their stimulating effects on the excretory and reflex functions of the skin, and the man who endeavors to avoid colds by avoiding all draughts will not only catch more than his share of colds, but will possess much less than his share of health and vigor.

Parental Alcoholism and Offspring.—M. D. Sturge and Sir Victor Horsley severely arraign the conclusions arrived at by E. M. Elderton and K. Pearson in the consideration of the wage-earning capacity of sober and drunken workmen respectively, and of the effects on offspring of alcoholism in their parents.

Unusual Case of Pulmonary Syphilis.—Von Hansemann showed before the Hufeland Society, Dec. 8, a case of syphilis in the lung of a newly born infant. As a rule hereditary syphilis of the lung is expressed as a white pneumonia, the lesions being constituted of gummata. In the present case, conditions differed greatly. The lungs were much enlarged, and the diaphragm depressed correspondingly. Tumor-like formations lay on the surface of the chest, and these greatly resembled cancer metastases. These neoplasms seemed to exhibit a thickening of the cellular tissue along with a thickening of the arteries. Amidst these tumor like masses portions of normal lung tissue were included. The lesions of white pneumonia, so often characteristic, were frequently noted. In the relatively sound portions of the lung, the septa were thickened (a diffuse gummatosis). The line between syphilis and tumor formation was hard to draw. It is of importance to

note that the pulmonary lesions were accompanied by various remote indications of constitutional syphilis—especially enlarged spleens and liver, but without specific deposits. There was a lesion in the myocardium, and a focus of syphilitic osteochondritis.

On the Short Ethyl Chloride Narcosis.—Behr discusses a time-worn subject from the modern standpoint as follows: The danger is reduced to a minimum. Patients testify that this resource is free from drawbacks. They declare also that the odor of the drug is agreeable to children—a matter of much significance. There are no sensations of suffocation, provided that the drug is properly given. Anesthesia quickly supervenes and quickly passes off. The rapid supervention of anesthesia and the rapid awakening therefrom, together with the absence of sequential symptoms serve to characterize this narcosis as a condition *sui generis*.

Unusual Forms of Bladder and Kidney Stone.—Roth, of Prof. Casper's Clinic, reports some very unusual cases of urinary calculi. To sum up the series, the author concludes that at times diagnosis, even with the most modern resources, is impossible. The *x*-ray may fail, and it is advised that in all suspicious cases the exposure should be repeated time and again. At best, given an *x*-ray shadow, we must have corroborative evidence—and some cases are quite free from symptoms. A routine cystoscopic examination may be advisable in all hematuric cases, as the source of the hemorrhage will thus be located, and therewith the seat of the stone. In so-called nervous bladder we should also use the cystoscope. In regard to renal calculus, any evidence of unilateral affection speaks first of all for the presence of stone.

Münchener medizinische Wochenschrift.

January 10, 1911.

Gastrospasm.—Waldvogel first speaks of the skepticism prevalent as to the existence of this affection, although prominent authorities believe that it may result from pyloric obstruction, pylorospasm, etc. The present writer goes to the extreme of believing that gastrospasm is the most frequent of all stomachic disorders. A result of motility disturbance, it is more constant than secretory anomalies, which so frequently change their character. The prognosis is good and the condition is controlled by very small doses of atropin. The condition may be very painful, the pain being controlled by hot compresses or a hot brick *in situ*. As the disorder appears to be a manifestation of neurasthenia, prolonged baths are useful, about blood heat. These should be taken daily and last up to three-quarters of an hour. In particular cases causal factors like onanism, nicotinism, etc., have been discovered. Arteriosclerosis is present in some cases, in which iodin should be given. Cases due to plumbism are readily cured by change of occupation.

Prodromes of Puerperal Thrombosis and Embolism.—Michaelis, realizing the apparent impossibility of foreseeing or preventing this condition, has investigated it afresh in connection with postoperative embolism and allied states. There is an undoubted relationship between the temperature and the disease; but the author is far from claiming the discovery of a new law. He does not necessarily associate a subfebrile temperature with a forthcoming thrombus. But he states that thrombosis and embolism do not occur suddenly, without prodromes; and that subfebrile temperature in the puerperium or after an operation may be regarded as at least a possible warning. The patients should at once be placed in absolute rest, especially as regards the possibility of mental shock. Early rising is of course strongly contraindicated. The diet should be light and oil enemata should be used to cleanse the bowels. The temperature becomes natural in about a week.

Successful Heart Massage after Apparently Fatal Narcosis.—Jurasz, of Prof. Payr's clinic, sums up a brief consideration of this subject as follows: Supposing that we have a sudden chloroform death and have devoted five minutes without success to the usual reanimating methods, the abdomen (epigastrium) should be opened at the median line and the heart grasped through the diaphragm between the thumb and two fingers. The heart should be then compressed rhythmically about sixty times to the minute. At the same time artificial respiration, oxygen inhalation, and the injection of medicinal heart tonics should be employed. The author reports one case in which eight minutes after syncope the patient was reanimated. Of especial interest is the fact that the interrupted operation (for cancer of the pylorus) was completed without further trouble. In other words what would have turned out to be a death on the table was averted. The patient recovered from the operation.

Generalized Syphilis in the Rabbit.—As is well known, rabbit syphilis was long regarded as a purely localized process, a result of inoculation of the cornea or testicle. Uhlenhuth and Mulzer seem to have succeeded in giving rabbits a general infection with spirochetes. These were introduced into the veins or in the heart itself. The experiments sometimes resulted negatively. The general picture of syphilis set up consisted of gumma-like nodules in the nose, tail, etc. When young rabbits were infected from children with hereditary syphilis, the picture was different. The animals wasted away, and developed a papuloulcerous syphilide, coryza, paronychia, etc. Living spirochetes were to be found in the blood. According to the authors these experimental findings mark an epoch in our knowledge of syphilis. The rabbit is far removed from man, yet like the ape can be made to receive syphilis. The spirochete now appears to be a blood parasite, able to cause a sort of sepsis. The questions of immunity, therapy, etc., should receive a fresh impetus, as well as the subject of heredity. The peculiar technique of the authors consisted in the intravascular injection of matter rich in spirochetes and freed from extraneous matter—the nearest approach to a culture.

Association of Fever with Malignancy of the Kidneys and Suprarenal Bodies.—Israel, the well-known authority on renal surgery has placed on record 14 cases of this association. He states that a fever may be set up by these tumors without any complication. This reaction may be early, intercurrent, or late. That is, fever is sometimes the first clinical evidence of the malady; or it may accompany the evolution of the disease; or it may be a terminal symptom. The type may be hectic, recurrent or one associated with hematuria; or the fever may be atypical. The reaction cannot be connected with liberation of bacterial toxins or absorption from necrobiotic tissues. It doubtless accompanies the evolution of all malignant growths, but the rationale is not clear.

Relationship Between Tabes and Leptomeningitis.—Astwazaturow describes a case which shows that what passes clinically for tabic crises may be of meningitic or syphilitic nature. Crises and universal pains which simulate tabes dorsalis may be due to active syphilis, a fact which opens up many possibilities. Since meningitis alone may cause pseudotabes, we have to consider the question of identity or association of these conditions. Naturally pseudotabes syphilitica or meningitis simulating incipient tabes should be amenable to treatment. It is generally believed that tabic crises are due to degeneration of the sympathetic fibers. But this does not exclude the fact that meningitis may be coexistent with inflammation of the posterior roots.

Book Reviews.

The Essentials of Materia Medica and Therapeutics for Nurses. By John Foote, M.D., Assistant Professor of Therapeutics and Materia Medica Georgetown University School of Medicine, Instructor in Materia Medica and Therapeutics Providence Hospital Training School for Nurses. Philadelphia and London: J. B. Lippincott Company, 1910.

This little work indicates a move in the right direction. The author tries to simplify the study of materia medica and therapeutics for nurses by limiting the number of remedies. As a rule his selection is judicious, and his discussion of the various drugs is quite adequate. But the chapter on solutions is too brief; the author uses the terms soda and sodium, magnesia and magnesium, ammonia and ammonium somewhat indiscriminately; and such terms as elixires, emulsæ, and infusæ should be eliminated.

Die innere Behandlung von Hautleiden. Von Dr. S. Jessner, Königsberg i. Pr. Dritte Auflage Würzburg. Curt Kabitzsch (A. Stubers Verlag), 1910.

This brochure of 49 pages deals with the subject of internal treatment of diseases of the skin, in a most comprehensive manner, that cannot fail to be of distinct service to the general practitioner.

Dermatologische Heilmittel (Pharmacopœa dermatologica). Von Dr. S. Jessner, Königsberg i. Pr. Dritte verbesserte Auflage. Würzburg: Curt Kabitzsch (A. Stubers Verlag), 1910.

He who would intelligently treat diseases of the skin must needs possess a clear understanding of the scope and nature of the remedies at his disposal. This volume of ninety-six pages presents a complete exposition of the dermatologist's medicinal armamentarium, carefully classified, with definite indications of the relative value of each medicament.

Pathogenic Microorganisms, Including Bacteria and Protozoa. A Practical Manual for Students, Physicians, and Health Officers. By William Hallock Park, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, and Director of the Research Laboratory of the Department of Health, New York City; and Anna W. Williams, M.D., Assistant Director of the Research Laboratory, Pathologist to the New York Infirmary for Women and Children. Fourth Edition, enlarged and thoroughly revised, with 196 engravings and 8 full-page plates. New York and Philadelphia: Lea & Febiger, 1910.

The title of this book does not adequately convey the broad and comprehensive manner in which the subject is presented. Rather than a mere description of the pathogenic microorganisms it is a complete exposition of the manifold relationship between them and the human organism. The morphology of the bacteria and protozoa is not the sole concern of the ideal textbook on the microorganisms. With the phenomenal developments of modern research, larger problems have arisen which would materially come within the scope of such a work. The elaborate theories of immunity with their numerous practical applications require full discussion. The authors have admirably fulfilled this requirement. The modification of older views with the acquisition of new information has necessitated in this edition the revision of such subjects as the relation of bovine tuberculosis to that of man, the value of antimeningococcus serum, the use of bacterial vaccines, the etiology of anterior poliomyelitis and trachoma, and the prevention and cure of trypanosomiasis. A chapter has been added upon the bacteria concerned in agriculture and in some of the important fermentations. The chapters on the colon-typhoid group of bacilli and on malaria are examples of a fuller treatment and rearrangement of material in the light of increasing knowledge. The description of the protozoa is given with a fullness commensurate with the growing appreciation of their important relation to disease. As a strictly up-to-date treatise this work answers the needs of both student and practitioner.

Syphilis. By Sir Jonathan Hutchinson, F.R.S., LL.D., F.R.C.S., Consulting Surgeon to the London Hospital and to the Royal London Ophthalmic Hospital, some time President of the Royal College of Surgeons. New and Enlarged Edition, with twelve colored and twenty-four black-and-white plates. New York: Funk & Wagnalls Company, 1910.

This work has been long known as a classic; but for some time it has been out of print, the new edition being delayed by the author's desire to obtain the fullest and latest knowledge from the demonstration of the *Treponema pallidum* as the parasite causing syphilis. The result of this delay seems to have been disappointing to the author, for he says: "The discovery had been so confidently foreseen, and had become by inference so definitely interwoven with the texture of our creed, that now that it has been actually made it brings us but little help." The book, however, is invaluable inasmuch as it contains over 500 pages of clinical histories, written with the utmost charm of style by one who for sixty years has enjoyed an unequaled wealth of clinical material. In the matter of treatment the author still prefers the administration of mercury by the mouth. He refers, however, to more modern methods, such as the arsenic salts. In the face of much that is new (and not always certain), such as the Wassermann and Noguchi reactions and the "606," it is well to hold fast to that which has been proved, and the modern physician may learn much from this recital of personal experience, extending over more than half a century.

A Manual of Obstetrics. By A. F. A. King, M.D., Professor of Obstetrics and Diseases of Women in the Medical Department of the George Washington University, Washington, D. C., and in the Medical Department of the University of Vermont, etc. Eleventh Edition, enlarged and thoroughly revised. Philadelphia and New York: Lea & Febiger, 1910.

From its first appearance, King's "Obstetrics" has occupied a prominent place among the works on the subject, and it continues to meet with the approval of students and practitioners. It will be found (or, rather, it has been found) to contain all that the student needs, and, as a rule, it supplies all requirements of the practitioner. In addition, it is written in a charming style, it contains no mere theories, and the illustrations are an aid to the understanding of the text, and not a mere collection of pictures. The book has long been an illustration of the fact that it is not necessary for a standard textbook to be of unwieldy size and enormous bulk. Additions to the present revision include: Pubiotomy, spontaneous version by posture, and the factor of thigh pressure upon the abdomen considered as one of the auxiliary forces of labor. The section on hyperemesis has been rewritten, and such other corrections and additions have been made as were deemed necessary. The book is brief and simple, but complete. We would suggest that in a future edition Plate I be inserted as it was in the last edition, in such a way that the illustrations and descriptive text may both be in view at the same time.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart, Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Philadelphia and New York: Lea & Febiger, September 1, 1910.

As usual, "Progressive Medicine" lives up to its title, and the present number is unusually interesting. The first instalment is on Diseases of the Thorax and Its Viscera, including the heart, lungs, and blood-vessels, by W. Ewart. Of particular value are the papers on Tuberculosis, and diseases of the blood-vessels. W. S. Gottheil contributes the section on Dermatology and Syphilis; E. P. Davis writes on Obstetrics, and W. G. Spiller on Diseases of the Nervous System. All of these contributors have been for years well known to the readers of this publication.

Hygiene for Mother and Child. A Manual for Mothers and Nurses, Including Hygiene for the Prospective Mother and Practical Directions for the Care and Feeding of Children. By Francis H. MacCarthy, M.D., Attending Physician to Out-Patient Department for Children, Massachusetts Homeopathic Hospital. New York and London: Harper & Brothers, 1910.

The large number of books dealing with the care of the baby have been isssued in response to a growing demand from an intelligent public. These books differ very little from one another. The present little volume is an eminently practical manual that can be entrusted to the mother or expectant mother. The multiplicity of details pertaining to the hygiene of maternity and to the care of the child renders a book of this kind welcome to the physician, whose place, at any rate, it cannot usurp. The chapters on infant feeding are sound, and that dealing with education and training in the home and at school reflects the mature wisdom and experience of its author.

Society Reports

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Twenty-third Annual Session, Held at Nashville, Tenn., December 13, 14, and 15, 1910.

THE PRESIDENT, DR. W. O. ROBERTS OF LOUISVILLE, IN THE CHAIR.

(*Concluded from page 176.*)

A Position for Saving Time in Combined Abdominal and Pelvic Operations.—DR. A. C. SCOTT of Temple, Texas, described this position as follows: By use of any metal knee-holder which fits comfortably in the popliteal space one might secure a combined exposure of the abdomen in an elevated position, and at the same time exposure of the pelvic outlet, permitting the use of self-retaining specula if desired. This was accomplished by having the popliteal knee-holder hinged on a short upright bar which was broadened and slotted at the lower end to slide, with a set screw upon a horizontal metal bar, which in turn was fixed to a strong cylindrical upright bar sliding in a vise-like clasp at the side of the operating table. The sliding upon the horizontal bar allows adjustment for the varying lengths of patient's thighs. The cylindrical sliding upright bar at the side of the table permits the thighs to be moderately flexed or fully extended, abducted or adducted at will. Before starting the anesthetic the patient's hips are brought beyond the edge of the table and the limbs placed upon the knee-holder. A piece of bandage loosely wound about each foot and ankle is tied to a convenient point below the corner of the movable part of the table to prevent extension of the leg; another is placed above each knee to prevent elevation of the knees, thus securely holding them in their respective knee-holders. Any modern operating table will serve the purpose for these attachments and enable one to secure the desired combined position if it has a pivotal point about the center permitting the entire surface of the table to be raised and lowered at will. He used a modification of the Markoe table, which operated with wheel and ratchet, and could be changed by the anesthetist with perfect ease. After the patient was in position and the anesthetic was begun the foot of the table was lowered some five or six inches for convenience or completing the preparation by thorough rinsing of the abdomen and vagina. This was done and the table returned to the horizontal plane without again having to take hold of the patient with the hands.

The advantages of this position were: (1) Where two operators were working together with plenty of assistants at their command the time required for many complicated operations might be reduced to a marked degree and often as much as 50 per cent. (2) By changing the axis of the table the pelvis and the abdomen might be lowered, if desired, or elevated, to secure the advantages obtained by the Trendelenburg position at any stage of an abdominal operation, without interfering with work simultaneously being done upon or through the pelvic outlet. (3) All the advantages of the Trendelenburg position might be obtained without its disadvantages. (4) All the advantages of the dorsal position for pelvic outlet work were obtained without flexing the thighs upon the abdomen or otherwise interfering with work required through the abdominal wall. (5) The final preparation of rinsing both the abdomen and vagina was easily accomplished while the anesthetic was being given, without having to lift or disturb the patient again. (6) By wide abduction of the extended thighs during abdominal operations room was made for a second assistant to stand with advantage for sponging, ligating, and retracting.

The Treatment of Anteflexion.—DR. HENRY T. BYFORD of Chicago stated he did not offer a new treatment. He asserted that the newest methods were not satisfactory, and selected for consideration one of the old methods and gave the essentials and technique that had given success in his practice. The method consisted in keeping the cervix over-dilated for six months to a year, and in the prevention, during the second year, of contraction sufficient to cause symptoms. The advantage of this method over all others consisted in keeping the uterus under the influence of the treatment until the cervix developed to a size that would not interfere with uterine drainage and cause symptoms, when the case could be compared to those of symptomless rigid anteflexion that one sometimes observes in multiparæ. He claimed that the cutting operations favored atrophy of the cervix and were irrational in most cases because the cervix was already deficient in development.

Complete Transverse Destruction of the Spinal Cord.—Dr. RANDOLPH WINSLOW of Baltimore read a paper in which he reported a case of complete transverse destruction of the spinal cord from pistol wound without penetration of the spinal canal; with a consideration of concussion as an etiological factor in the production of this lesion and of the question of suturing the cord when it was completely divided. He narrated two cases of pistol wound of the dorsal vertebræ in which the cord was not injured by direct impact of the bullet, but in both of which paralysis and the usual signs of a transverse destruction of the cord immediately supervened, proving fatal in one case, which came to autopsy, and the bullet was found lodged in the second dorsal vertebra, but not penetrating into the spinal canal or impinging on the cord. The other case presented similar symptoms, and were submitted to laminectomy, but the cord was not divided, nor could the missile be found. He was still living, but was in a very precarious condition, with absolute paralysis below the eighth dorsal vertebra. These cases were thought to have been due to concussion of the cord. The views of a number of military surgeons and authors were quoted in regard to the production of the lesions of the cord by concussion without direct impact on the spinal cord who were unanimous in the belief that such injuries did occur. The question of suturing the severed spinal cord was discussed, and several operations of this character in the hands of other surgeons were mentioned. The results had not been good, and physiologists declared that regeneration of the severed spinal cord was impossible. Be this as it may, marked improvement followed in one case, and there was no reason why the cord should not be sutured in appropriate cases. Dr. Winslow summed up his views upon these questions as follows: (1) That serious and even fatal lesions of the spinal cord might be produced by concussion, without direct impact. (2) That in gunshot injuries, with a probability of a complete severance of the cord, laminectomy should be performed, foreign bodies and clots removed, bleeding arrested, and if the cord had been divided the separated ends should be approximated with sutures. (3) Care should be exercised not to destroy any nerve fibers or tracts which might still be intact.

An Unusually Large Ovarian Cyst.—DR. J. SHELTON HORSLEY of Richmond, Va., reported a case (and showed photographs) of a large ovarian cyst which weighed 116½ pounds. The greatest abdominal circumference was 63 inches. The cyst was successfully removed. He referred to the fact that operation in these cases of large ovarian cysts usually had a high mortality rate on account of the pressure, which caused organic changes and made the patients poor surgical risks.

DR. THOMAS S. CULLEN of Baltimore stated four and a half years ago he saw a patient who weighed 174 pounds.

She was supposed to have had an ovarian cyst, but it turned out to be a fibroid tumor. They operated, removed an 89-pound fibroid, and the patient immediately after operation weighed 85 pounds. After a week in the hospital, when edema began, she weighed 80½ pounds, and although she developed bed sores she promptly recovered. In that case after operation the ribs stuck out six inches and the recti muscles, which lay high up on either side, gradually came together until at the present time they were only 2 cm. apart.

Dr. Alexander Hugh Ferguson stated he was called to a small town near Indianapolis to see a woman with a large ovarian cyst. She had carcinoma of the left breast and gallstones. She was in a bad condition. He introduced a small trocar and cannula which went into a cyst that was quite watery. The trocar was left in place for twenty-four hours. The next day she was able to eat, a thing she had not been able to do for two weeks, and was able to swallow. Her heart, which was bad, improved. He passed a large trocar in another direction through the same opening and allowed it to remain for another twenty-four hours, and then she was brought to Chicago, and three days later he operated and at one sitting removed the cyst, the left breast, and 1,250 gallstones from the gallbladder, and she recovered.

A Malignant Intestinal Growth Requiring the Removal of an Unusual Number of Abdominal Structures.—Dr. Thomas S. Cullen of Baltimore, in his paper, reported the case of a patient, fifty-six years of age, very pale and emaciated. Within a few years prior to operation her weight had been reduced from 120 to 85 pounds. Pelvic examination revealed a growth plastered on the posterior surface of the uterus. This almost filled the pelvis, and felt very much like a myoma. The patient, however, gave a history of flattened stools, occasionally associated with diarrhea, and a malignant intestinal growth was suspected. On opening the abdomen Dr. Cullen found a growth involving the lower portion of the descending colon, also a loop of small bowel, and extending out and forming a tumor mass in the mesentery of the small bowel. Intimately blended with this tumor mass was the uterus. The appendix was also involved. As the patient's condition was very poor the operator hesitated to do anything, but the family physician said that she could only live a few days in her present condition, and that she was suffering a great deal. As no secondary nodules could be found, either in the mesentery, in the lymph glands, or in the liver, removal was undertaken. The uterus was amputated through the cervix and with the tubes and ovaries turned up on the surface of the tumor. The appendix was next amputated, carefully covered over with gauze, and also turned up on the tumor. About three feet of small bowel and almost a foot of large bowel were then clamped off and the mesentery of the small bowel containing the tumor gradually tied off. All the structures mentioned were removed in one piece, as it would have been absolutely impossible to separate the uterus without entering the cancerous mass and opening up the bowel. It was possible to remove the entire mass without soiling the peritoneum. The four ends of the bowel were closed. A lateral anastomosis was then made between the small bowel and the cecum, and as the descending colon had been redundant it was possible to do a lateral anastomosis between the descending colon and the sigmoid. A drain was laid in the pelvis. The specimen was exhibited. The patient made a very satisfactory recovery, and was at present in good health. The ultimate outlook was not a favorable one.

Aneurysm.—Dr. J. Garland Sherrill of Louisville reported a case of aneurysm, and described a new method of ligature of the left subclavian. From a study of the reported cases and his own work the following conclusions were drawn: That ligature of the subclavian artery in the first portion of the right side showed a higher mortality than the left. This was probably due in part to the short distance between its origin and the first branch, and also to its close relation to the pneumogastric nerve, thoracic duct, and the internal jugular vein. The mortality of ligature in the second division is 55.5 per cent.; in the third division, about 50 per cent. The mortality was greater when ligature was done for injury to the vessel than for aneurysm. With present methods the mortality of ligature in any portion of the subclavian should be greatly reduced, as was shown by recent results of Halsted, Schumpert, Jungst, and Curtis. Distal ligation had not proven satisfactory. When the aneurysm was situated high on the axillary artery or upon the distal portion of the subclavian the anterior operation should be employed when the vessel was accessible. The method here described was offered for the treatment of those cases in which the aneurysmal tumor encroached upon the tissues of the neck in such a way as to preclude the possibility of ligation by the anterior method. He had found that at the origin of the left subclavian from the arch of the aorta there was no danger of including the pneumogastric nerve in the ligature or of damaging the thoracic duct.

Goiter Operations.—Dr. John R. Wathen of Louisville described an improved technique in goiter operations based upon an experience of 142 operations for the different types of goiter, with no case of injury to the recurrent laryngeal nerve or any clinical evidence of injury to the parathyroids. The use of the scissors had replaced the knife entirely, and all the structures, beginning with the skin, and later the enlarged thyroid gland, were elevated and approached from the under surface. This lessened the hemorrhage by placing the parts on the stretch, made the work more rapid and safer, and allowed of easier blunt dissections being made. The neck was opened by pinching up the skin with the fingers and making a small cut through the skin and the platysma. The cut surfaces were now grasped by vulsellum forceps and traction was made upward; next blunt-pointed, curved scissors were used as a dissector, and the skin, with the attached platysma, was rapidly separated from the muscles below and then cut along the curved line used by the Kochers. By continuing the upward traction the two large skin flaps were dissected up to the hyoid bone above and to the sternum below. The ribbon muscles were now separated in the middle line and clamped high up and cut on one or both sides when needed, as had been suggested and practised by Dr. C. H. Mayo. The fibrous and the true capsule over the goiter was next opened, and with a large pair of vulsellum forceps the enlarged lobe was elevated and traction was made in an upward direction and to the opposite side of the neck. This readily allowed the capsule to be dissected downward and placed the blood-vessels to be ligated on the stretch, causing less venous hemorrhage and relieving the trachea of the pressure from the weight of the tumor. The vessels could now be clamped, as the elevated goiter lifted them away from the surface of the capsule. The capsule adherent to the posterior structures was thus separated from the vessels, and there was no danger of the nerve being included with the vessels or any danger of injuring the parathyroids. Occasionally, when the enlarged lobe extended high up in the neck, it was better to place on a second vulsellum forceps on the upper part and make traction upward and downward to better expose the superior thyroid artery and vein. This constant upward traction on the tumor allowed it to be rapidly dissected from the posterior structures and only held by the isthmus of the gland. A large clamp crushed this part which could be sutured over. The capsule, muscles, and skin were now closed in the usual way and

drainage provided through a stab wound in the lower flap. This technique differed from that of others in that it did not employ the knife, which was dangerous in neck surgery; it cut the skin and superficial structures only after they had been elevated and dissected up from below, and it grasped the goiter with vulsellum forceps and elevated it away from the dangerous area underneath. This constant traction caused much less hemorrhage and allowed of a rapid operation, within plain view of the surgeon. It was surprising how few forceps were used when the venous hemorrhage was thus controlled.

Collapse of the Trachea While Performing Thyroidectomy.—Dr. T. C. Witherspoon of Butte, Montana, said that during the last fourteen months he had twice had the trachea collapse while performing thyroidectomy for exophthalmic goiter. The predisposing cause of collapse of the trachea was the anatomical defect in the rings posteriorly. This allowed the lateral walls to approach closer under pressure and to change the cross section of the tube from a circle to an oval, with its long diameter anteroposteriorly. Another factor influential in starting a collapse was the proximity of the recurrent laryngeal nerve to the thyroid gland. It was possible that more or less softening occurred from the toxic effects of the gland secretions. The one prophylactic measure which he suggested as a means of avoiding pressing upon the trachea was a para-sterno-cleido-mastoid incision. This enabled the operator to raise the gland out of its bed without medianward pressure of appreciable degree. No doubt a collar incision with enucleation from between the sternohyoid and sternothyroid muscles of either side necessitated considerable pressure upon the trachea. While working out the problem of removal of the thyroid under local anesthesia he found it very much easier to do so by the paramuscular than by the collar incision. Manipulation was easier and discomfort minimized. He experimented upon the cadaver in developing a technique, and removed over twenty goiters under local anesthesia before using a general anesthetic. This was excluding his first case, operated upon in the early nineties, to which chloroform was given. Of late years he had used the collar incision, possibly modified slightly, but he was rather of the opinion that his former plan of paramuscular incision gave a better field, made operating easier, and did not leave an ugly scar. He believed this incision would prove a valuable prophylactic against tracheal collapse.

Catheterization of the Common Duct as a Practical and Effective Upper Route for Enteroclysis Medication in Toxic Biliary Cases (McArthur's Procedure).—Dr. Rudolph Matas of New Orleans related his experience with this operation, and said it was a conclusive demonstration of the good effects of this mode of procedure. It convinced him that it constituted one of the most valuable therapeutic assets in dealing with the dangerous postoperative complications of biliary cases. Since his first experience he had had occasion to try it in another case of choledochus drainage after cholecystectomy or gangrenous and perforated gall-bladder. In this case, notwithstanding the excellent effect on the circulation of the duodenal infusion, which was liberally applied, the patient succumbed on the fifth day from the effects of general peritoneal sepsis and exhaustion due to secondary pulmonary infarcts. He had also applied it in three other cases, two referred to him by other surgeons, of persistent biliary fistula, after cholecysteotomy for multiple calculi and cholecystitis. In these cases he had been surprised by the rapid cure of the fistulæ after repeated catheterization of the biliary tract, including the duodenal orifice of the common duct. In no case had he had occasion to apply the simple procedure recommended by McArthur, which was to connect a saline drip to a drainage tube in the gall-bladder, thus allowing the water to find its way into the duodenum via the cystic duct. This was a very simple performance, but in all his cases he had preferred to inject the fluid directly into the duodenum by introducing a catheter through the gall-bladder opening into the common duct and then into the duodenum. For this purpose he had found nothing so effective as a ureteral catheter, beginning with a fine bougie and gradually dilating with the catheters until the number three of the French scale had been reached.

Some Suggestions Relative to the Preparatory Operative and Postoperative Treatment of Cases of Acute Intestinal Obstruction.—Dr. John Young Brown of St. Louis, Mo., stated in this paper that an analysis of the records of 59 cases of acute intestinal (mechanical) obstruction, coming under his care with the view of ascertaining the treatment received in each case prior to operation and the bearing this treatment had on the mortality, had convinced him that the general profession had yet to appreciate that acute intestinal block was one of the gravest and most disastrous surgical emergencies, and that the outcome of a given case depended largely upon the time elapsing between the development of the condition and its relief by surgical interference. Of the 59 cases recorded 27 required primary resection for gangrene of the bowel. All of these cases save one resulted from strangulation due to hernia, the exception being due to a gangrenous intussusception. Of these 27 cases 5 died, giving a mortality of a little over 20 per cent. In 12 cases the formation of an artificial anus was necessary. Three of these were for strangulated umbilical hernia, 4 for strangulated inguinal hernia, and 5 were for acute obstruction due to malignancy. Of these 12 cases 6 died, giving a mortality of 50 per cent. Twenty cases of strangulated inguinal hernia in which the contents of the sac was such that it could be returned to the abdomen resulted in the loss of 1 case, a mortality of 5 per cent. The total mortality in the 59 cases was a little over 20 per cent., a mortality entirely too high, and largely due to conditions avoidable. The history of each case, without a single exception, showed that temporizing methods were resorted to prior to operation. He illustrated this by selecting two cases at random from the list, one operated on 52 hours after strangulation, the other 72 hours. Gangrenous bowel was found in each. Taxis, cathartics, and morphine, with hot applications to the abdomen, had been used in each case, the cases being referred to operation as a last resort. That the general profession still used such methods was not to be wondered at. Surgery, to be successful, must recognize two factors always present in acute intestinal blocks: First, and least important, was the mechanical block in the bowel, the actual obstruction. The second, and incomparably the more severe, was the septic absorption from the distended, congested, and perhaps ulcerated bowel above the place of stoppage. After urging careful preparation of the patient with particular attention to the removal of the stomach contents by means of the stomach tube, he described a method of draining a distended bowel above after the constriction was relieved. In the treatment of gangrenous bowel found in the sac of a femoral hernia he strongly advocated the use of a supplementary abdominal incision as possessing many advantages when it became necessary to resect the gut. In discussing the postoperative treatment of such cases he advocated frequent washing of the stomach, the withholding of food by the mouth, and the use of salt solution, both under the skin and in the rectum, and he condemned in strong terms drugs in the way of morphine and strychnine. In cases where an artificial anus had been made he urged the importance of attention to the passive bowel. He illustrated with the report of two cases how failure to attend to this point in the after-treatment could result in a contrature of the small bowel to such an extent

that it would complicate the work of restoring the intestinal continuity.

Cysts of the Pancreas.—Dr. Rufus B. Hall of Cincinnati detailed his further observations on this subject. He reported to the association a case of cyst of the pancreas in 1907, and now reported another case of equal interest which emphasized the great importance of early operation in these cases.

President's Address.—Dr. W. O. Roberts of Louisville delivered an address which was literary rather than scientific, and dealt biographically and historically with the names and achievements of the prominent men who practised surgery in the South before, during, and after the Civil War. It covered the period of years between 1806 and 1892, from the pioneers of the first two decades of the nineteenth century to the few who survived and did work in the last two decades. These names might be divided into two, perhaps three, groups. First, the pioneers; second, the general surgeons; third, the founder of the specialties. In the first are Walter Brashear, Ephraim McDowell, Charles McCreary, and Benjamin Winslow Dudley. These the author ranked as pioneers in American surgery. One of them, Dr. McDowell, was an epoch-making surgeon. The others in early days were conspicuous in the surgery of the South, and did marked and original work, adding much to the medical fame of Kentucky, which was the field of their labors. They were all accomplished physicians as well as able surgeons, and with wonderful industry, learning, and art practised successfully medicine in its three great specialties, as laid down by Hippocrates, namely, medicine, obstetrics, and surgery. In those days little beyond minor surgery was done by the country doctor, and the physicians of the larger towns and villages sent their more important cases to the cities, where the men named performed the necessary operations. The specialties of surgery during that period were merely taking form, or being slowly differentiated, and it might be said that these men, while practising general medicine and doing high class surgery, did much of the work now done by specialists, and, in short, helped to form and differentiate the specialties. Some of them, indeed, were its real pioneers. The list being a long one, Dr. Roberts selected a few only for special comment. They were Hunter McGuire, Paul F. Eve, W. T. Briggs, Warren Stone, J. Marion Sims, Samuel D. Gross and David W. Yandell. He gave a detailed biographical sketch of each of these surgeons. The speaker's peroration was reflective, retrospective, and eloquent.

Cancer of the Uterus.—Dr. Reuben Peterson of Ann Arbor described the technique of the radical abdominal operation for uterine cancer, based upon an experience with forty-four cases.

Dr. Willard Bartlett of St. Louis presented an interesting series of lantern slides of distinguished surgeons of Great Britain, of the surgical clinics visited, of the operations performed by these surgeons as witnessed by the members of the American Clinical Society.

Volvulus of the Cecum.—Dr. Horace J. Whitacre of Cincinnati reported four cases of volvulus of the cecum, and gave a brief statement as to the nature and frequency of the lesions. In case one, a very movable cecum and ascending colon had passed over in front of them completely around, behind the mesentery of the small intestine, and reappeared in the right side. This patient had suffered three previous similar attacks of obstruction of the bowel which had been relieved by enemata and position. This patient recovered after operation. Cases two and three represented volvulus of the cecum and ascending colon alone, gangrene having occurred in both. One of these patients recovered. A fourth case suffered from volvulus of the cecum and ascending colon, was operated upon in a very few hours, and made a prompt recovery. Volvulus of the cecum is among the least frequent causes of intestinal obstruction. It had occurred at all ages from sixteen days to eighty years. The symptoms, as a rule, did not differ widely from those of intestinal obstruction from other internal cause. Some authors spoke of a false remission of symptoms after the first two or three days. The mortality was very high, even in cases operated upon (52.2 per cent.). The cases reported by the author seemed to present symptoms that were suggestive, namely, first, all suffered premonitory symptoms or previous attacks. Second, all cases presented primary symptoms in the region of the cecum, and a localized distention first appeared at this point. The mortality in this group of cases was 25 per cent.

Pylorospasm.—Dr. Stuart McGuire of Richmond said that spasm of the pylorus or pylorospasm was not a disease, but a symptom. It might be caused by rapid eating, by indigestible food, by an ulcer or other lesion of the stomach, but was most frequently the expression of some remote abdominal disease. How appendicitis or cholecystitis caused gastric symptoms had never been satisfactorily explained. It was believed that irritation transmitted to the stomach through the sympathetic nervous system caused an excess secretion of hydrochloric acid. The resulting hyperchlorhydria caused spasm of the pylorus; the pylorospasm caused retention of food beyond the physiological limit, and finally there came motor insufficiency, food stagnation, and dilatation of the stomach. The most prominent symptom of pylorospasm was a cramping pain in the epigastrium, which might last only a few minutes or might continue for several hours. In some cases the spasm might relax suddenly; in others it might terminate slowly and gradually. Some patients had attacks several times a day; others at intervals of weeks; and others still only once or twice a year. In the interval between attacks the digestion may be normal. During attacks peristalsis of the stomach was increased, but food could not pass through the pylorus, and often relief came only after vomiting. The patient usually dieted strictly and lost flesh and strength steadily from starvation and autointoxication. In no other class of patients, with possibly the exception of epileptics, was it necessary to be so thorough in preliminary examination and so patient in postoperative treatment. The real cause of the condition must be found, and after it had been removed the patient must be systematically treated until the hypersensitiveness of the pyloric muscle was relieved and its spasm habit overcome. After reporting an interesting case Dr. McGuire emphasized the following points: (1) The necessity of differentiating between gastric symptoms due to organic disease of the stomach and those reflex from other organs. (2) The impropriety of doing a gastroenterostomy for spasm of the pylorus. (3) The advisability at the time of operation of examining all abdominal organs and correcting every abnormality, lest the obvious might not be the real cause of the symptoms. (4) The importance of the postoperative and posthospital treatment of patients to overcome the spasm habit of the pyloric sphincter.

Tumors of the Jaw.—Dr. Willis F. Westmoreland of Atlanta presented the pictures of a type of tumor that so far as his clinical experience went had practically disappeared. He had not seen one in years. This type of tumor seemed to have occurred almost exclusively in the negro. In thirty-eight cases operated upon by his father only one was white. In the five cases occurring under his observation all were in the negro. Among us these cases were known as fibrocystic tumor; this title very closely described the gross clinical appearance of the tumor. In reviewing the literature of this subject Dr. Westmoreland said: "I am not able to place it, though it seems to conform more closely to the species of follicular odontoma

of the genus odontomata in Bland Sutton's classification. I would class it as an anomalous form of this species. I should judge they belong to the follicular rather than the epithelial odontoma, although they have never shown malignancy, while the epithelial type occasionally did." Clinically the tumors present a uniformly well-rounded mass, the surface of which felt hard and dense to the touch. Firm pressure upon the tumor with the fingers would always at some point elicit a distinct crackle; that was characteristic, as in a way diagnostic, though not differentially so as it occurred in other species of odontoma. In a research of the literature of tumors of the jaw, which up to a few years ago were classified under the generic term of dentigerous cysts, the essayists had probably had the same trouble as he had, seeing them in their later development and being unable to properly classify them. But in the negro one fact seemed to be true, and that was, no matter what the original type, the later development was always along the same line.

Transfusion in Pellagra.—Dr. H. P. Cole of Mobile, Ala., presented a review of twenty cases of this disease, and then drew the following conclusions: In the transfusion of twenty cases of pellagra they had found no ill effect resulting directly from the operation. They might safely resort to transfusion in the severe type of case steadily retrogressing under approved therapeutic procedures. They had noted no advantage in the employment of a donor who had recovered from pellagra, as compared with the donor who had never had pellagra. There was apparently no advantage in the use of a relative for a donor as compared to the use of a non-relative. The recoveries following transfusion in the grave type of cases (60 per cent.) compared most favorably with the recoveries (10 to 20 per cent.) in the same type of cases in which other therapeutic measures were employed. The employment of transfusion in the terminal stages of pellagra must be undertaken with a full knowledge of the difficulties and dangers of the operation. Without careful selection of the cases and unprejudiced conclusions this procedure would fall into an undeserved illrepute.

The Causal Relationship Between Injury and Cancer.—Dr. William B. Coley of New York stated that in a previous paper (*Annals of Surgery*, March, 1898) he published an analysis of 170 cases of sarcoma that had come under his personal observation, and stated that no clinical feature of the disease had impressed him more strongly than the frequent association of trauma with its early manifestations. In 46 of these 170 cases there was a definite history of antecedent trauma. Since this paper was written he had observed 740 additional cases of sarcoma, making a total of 910 cases. In 236 cases (26 per cent.) there was a definite history of antecedent trauma. The interval elapsing between the injury and the development of the trauma was less than two weeks in 63 cases (27 per cent.); less than a month in 97 cases (42 per cent.); tumor occurred within the first six months in 137 cases (60 per cent.). The disease originated in the bone in 111 cases (47 per cent.) and in the soft parts in 125 (53 per cent.). In making a study of all his cases of carcinoma he presented an analysis of 125 cases of carcinoma of the breast. In these there was a definite history of previous injury in 52 cases, or 41 per cent. In 5 of these the tumor was noted within a week after the injury; in 12 cases within the first few weeks; in 19 within the first month, and in 36 within the first six months. He further presented three cases that had come under his personal observation which fulfilled the strict, scientific test which Segone required, namely, that a medical examination had been made of the parts by a competent surgeon prior to the accident. He did not attempt to offer a complete explanation of the influence of injury upon the development of malignant tumors, but said that he personally believed more strongly with increasing experience that all types of malignant tumors were of extrinsic origin or parasitic.

The following papers were also read: "Hydatid Cyst of the Liver Successfully Treated by Operation," by Dr. John C. Oliver, Cincinnati; "Diagnosis of Extrauterine Pregnancy," by Dr. E. Gustav Zinke, Cincinnati; "Omenopexy," by Dr. Maurice H. Richardson, Boston; "Tumors of the Breast," by Dr. William C. McCarty, Rochester, Minn.; "Hypernephroma Arising in the Right Testicle," by Dr. James E. Thompson, Galveston, Tex.; "Degeneracy, the Underlying Cause of Disease: How the Unfit Perish," by Dr. Chas. P. Noble, Philadelphia, Pa.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Rudolph Matas, New Orleans; *First Vice-President*, Dr. Guy Leroy Hunner, Baltimore; *Second Vice-President*, Dr. J. Garland Sherrill, Louisville; *Secretary*, Dr. William D. Haggard, Nashville; *Treasurer*, Dr. William S. Goldsmith, Atlanta.

Washington, D. C., was selected as the place for holding the next meeting. Time, December, 1911.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Special Meeting in the Borough of the Bronx, Held January 9, 1911.

Dr. N. B. Van Etten in the Chair.

Electrocardiograms and Their Significance.—Dr. Thomas E. Satterthwaite presented a paper with this title (see page 189).

Dr. Alfred E. Cohn said that the apparatus described was now in use in various places in New York and elsewhere in this country. Personally, he was inclined to take a more favorable view of electrocardiograms than Dr Satterthwaite. In fact, they seemed to him to offer a great many advantages. The well known difficulty in getting tracings of the venous pulse and the difficulty in writing them was by this method absolutely done away with. Practically, he had found that it made no difference whether the patients were thin or fleshy. Moreover, one had the advantage that the patient might be at almost any reasonable distance from the instrument. Thus, at the Mount Sinai Hospital the patients in whose cases the method was employed were in all parts of the medical pavilion. Not infrequently the examinations were carried on for as much as two hours at a time, yet without the slightest discomfort to the patient. As to just what conditions could be diagnosticated by means of electrocardiograms, would require more extended demonstrations than were possible at the present moment.

Dr. H. B. Williams said that this was an instrument of precision, but it did not follow from this that by it we could diagnose valvular lesions. This was possible in so far only as such lesions gave rise to changes in the cardiac muscle. The method enabled one to get a positive expression of the muscular activity of the heart, and this was something which one had not previously been able to obtain. Again, heart-block could be more easily diagnosticated by this means than by the polygraph. This instrument, he believed, would never come into general clinical use, but its installation in various medical centers, it was to be hoped, would enable practitioners to avail themselves of its advantages in difficult cases. Its principal use, however, would no doubt be as an instrument of research

Dr. Louis F. Bishop said his impression was that the work now being done in this department of research in New York and in America in general was at least as good as that in Europe. During the past summer, while in Nauheim, he had had the opportunity of studying the system of electrocardiograms, and he was convinced that in the class of cases to which it was adapted the instrument

was a valuable addition to our resources. The apparatus, however, was very complicated, and there would always be found some patients on whose cases it would not throw any light. Electrocardiograms were chiefly valuable in tracing and exploring various irregularities of the heart muscle. In New York he had not yet had the opportunity of employing this method of investigation, but within the last ten days he had met with two patients in whom he believed it would have proved of service. In one of these there was apparently an hypertrophy of the right ventricle, and in the other, dilatation of the right heart following emphysema of the lungs. In both instances, he believed, hypertrophy of the right ventricle could have been positively demonstrated by means of electrocardiograms. In Germany the instrument was successfully employed to show the extra systole, and in extra systole, heart-block, and hypertrophy of the right ventricle it usually gave satisfactory evidence. Dr. Bishop thought that one point brought out by the last speaker was a most valuable one, namely, that in clinical work it would be of great assistance to have those instruments in medical centers, where physicians could avail themselves of the aid in diagnosis which electrocardiograms afforded. He had always wondered why medical men did not combine together more. If several hundred of them would purchase a set of these instruments, and engage an electrical engineer to manage the mechanical part of the work, he believed it would be of great advantage to all concerned.

Dr. Reynold Webb Wilcox said that as this was an assemblage of various instruments, and it was difficult to get such a collection satisfactorily adjusted and working together, it certainly seemed to require great care to secure records with it. Personally, he believed the Grödel method, which was the older method, was preferable. But how any instrument, however ingeniously constructed, could make a complete diagnosis without the physician's mentality it was difficult to see. The apparatus under consideration, however, was of service in that it explained certain facts of the existence of which we were already aware; and, although the mechanical difficulties attending its employment were great, he believed it would become a valuable feature in laboratory work.

The Diagnosis of Empyema, with Special Reference to the Physical Signs.—In this paper Dr. Howard H. Mason considered two main groups of empyemas: those in which the pus is free in the pleural cavity and those in which it is restricted to one or more portions of the pleura. In treating of the latter he dwelt particularly on the differential diagnosis from subphrenic abscess, and in summing up he emphasized three points: (1) the possibility of empyema in those cases of pneumonia which do not clear up satisfactorily; (2) the fact that an empyema may be situated deeply and give rise to few, if any, local signs; (3) the desirability of employing the *x*-ray and repeated punctures in every doubtful case, if necessary to find the pus.

Subphrenic Abscess.—Dr. Henry Roth read an elaborate paper on this subject, and in the course of it he narrated four cases at the Lebanon Hospital in which he had operated with successful results. In the first of these, that of an Italian 23 years old, with an alcoholic history, the subphrenic abscess was believed to be secondary to hepatic trouble. The second case, in an adult female, belonged to the small group in which the abscess develops from pelvic inflammation. In the third patient, a boy of 8 years, the abscess had its origin in an appendicitis. The fourth case, in a female, also resulted from appendicitis, and in this instance the abscess was on the left side, a very rare circumstance in subphrenic abscess due to this condition.

These two papers were discussed by Drs. Wilcox, Van Gieson and Gallant.

Philadelphia Neurological Society.

At a stated meeting, held December 23, Dr. Francis X. Dercum presented "A Case of Cerebrospinal Sclerosis with Symptoms of Cerebrospinal Syphilis." The patient was a man about thirty-eight years old who presented delay in micturition, difficulty in walking, exaggerated kneejerks, ankle-clonus, Babinski sign, ataxia, disturbance in speech, nystagmus, without definite history of syphilis and without Wassermann reaction. Dr. Dercum presented also "A Case of Tabes in a Negro." The patient was a man about thirty-four years old with absent kneejerks, delayed sensibility, static and motor ataxia, optic atrophy, and blindness. The ataxia that was present when the eyes were open became more pronounced when the eyes were closed, in spite of the optic atrophy and the blindness. On inquiry it was found that there was a strain of white blood in the patient's ancestry. Dr. Dercum presented also "A Case of Astasia-Abasia." The patient was a man about forty-two years old, a waiter who had had diphtheria many years before, with difficulty in swallowing. Following the loss of some money the man developed difficulty in walking and in standing, although he could perform all movements in the recumbent posture. For a time there was unilateral hypesthesia, first upon one side and then upon the other. The reflexes were preserved. Under training there had been great improvement, so that the patient was able to walk, but, as he continued, with increasing unsteadiness and insecurity, until finally he fell in a heap. The condition was looked upon as hysterical. Dr. T. Turner Thomas presented a communication entitled "Falling of the Humerus Associated with Dislocation of the Shoulderjoint and Paralysis of the Arm." He reported a small group of cases presenting a condition of apparent paralysis of the deltoid muscle of circumflex origin and in which he was able to afford relief by exposing the capsule of the joint and repairing lacerations found therein. Dr. Alfred Gordon presented a communication entitled "Psychoanalysis as a Therapeutic Procedure in Psychoneuroses." He elucidated the psychoanalytic method of Freud, pointing out that it is the opposite of suggestion, and he cited an illustrative case in which the discovery of the underlying subconscious factor and its projection into the domain of consciousness permitted of explanation that brought about a cure of a long standing disorder that had resisted other methods of treatment.

Results of the Ligature of the Suprarenal Vessels; Contribution to the Study of the Suprarenal Toxins.—Umberto Luigi Torrini gives us the results of an experimental study of the suprarenal toxins, and the result of ligature of the suprarenal vessels. The author states that the parenchymal elements of the suprarenal capsules set at liberty cytotoxins that are absorbed by the blood, and act principally on the blood vessels, producing alterations in the circulation, such as stasis and hemorrhage. These toxins, either directly or indirectly by alterations of the vessel walls, cause changes in the glandular elements themselves. The liver and kidneys studied systematically show degenerative changes and a process of more or less extended sclerosis. The effects of these cytotoxins diminish gradually. From a second series of experiments he shows that ligature of the suprarenal vessels produces disturbances of the circulation such that in a short time we have degeneration and necrosis of the cellular elements of the suprarenals, and the cytotoxins rapidly pass into the circulation. These alterations take place in the opposite suprarenal as well, and in the kidneys and liver, in which there is fatty degeneration of the glandular epithelium. A sclerosis of the gland itself takes place, and a slow sclerosis takes place in the opposite suprarenal gland, in the liver, and in both kidneys.—*La Sperimentale.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Medical Items.

A Case of Postoperative Parotitis.—Carcía Casariopo describes a case which occurred in a male patient that had been operated on for appendicitis. A month after the operation the parotid gland became swollen and greatly inflamed and an abscess formed, which was opened. The *Staphyloccocus pyogenes albus* was found in pure cultures in the pus.—*Crónica Médico-Quirúrgica de la Habana.*

Foreign Bodies in the Ear of the Insane.—F. M. Fernández calls attention to the great frequency with which the insane have foreign bodies in their ears. This is in contrast to the eye where few are seen. The causes given are: greater frequency of auditory hallucinations, desire to ameliorate some previous ear affection, the greater facility the ear affords for the lodging of foreign bodies, and the tolerance of the ear for them. Of forty cases reported only two had some complication after the extraction, otitis media being present in both. During the extraction only one case presented serious difficulty for the dislodging of the foreign body and chloroform was required.—*Crónica Médico-Quirúrgica de la Habana.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended January 27, 1911.

ADDRESS OF THE RETIRING PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.*

BY JOHN A. WYETH, M.D., LL.D.,

NEW YORK.

IN rendering an account of my stewardship, after first expressing my full appreciation of the very great honor conferred upon me in 1906, an honor emphasized by an unexpected reelection in 1908 for a second term, I wish to acknowledge the great obligation I and every other member of this organization am under for the faithful and efficient service rendered by the Trustees under the leadership of the Nestor, not only of the New York Academy of Medicine, but of the medical profession in America, our venerable and beloved Dr. A. Jacobi; to our efficient Treasurer, Dr. Reginald H. Sayre; to the Secretary of the Trustees, Dr. A. M. Jacobus, who has so long and faithfully filled that office; to the Council and to the Committee on Admissions, ever on the outlook for the best interests of the Academy; to the Library Committee, whose onerous duties have been so well performed, to the Chairmen, Secretaries, and members of the Sections, and to Assistant Secretary Dr. C. F. Adams,, who has cooperated so satisfactorily with the President in making up the programs; to our Librarian and Superintendent, Mr. J. S. Brownne, whose long service and great experience have made him an integral part of our organization; to his faithful assistants in every capacity, and last, but not least, to Dr. John H. Huddleston, our Secretary, ever faithful, helpful, and courteous. I cannot feel that my official task is completed without this heartfelt recognition.

In the 63 years of the Academy's history only five of its Presidents have served for more than two years. From 1847 to 1859 the official term was one year, and during this period only Doctors Valentine Mott and Isaac Wood served two separate terms of one year each. The first two-year term was in 1859-60, when Dr. John Watson was made President. During the Civil War, from 1861 and up to the year 1866, Dr. James Anderson served three successive terms of two years each. From 1867 to 1874, inclusive, Doctors Alfred C. Post, Henry D. Bulkley, Edmund R. Peaselee, and Austin Flint, the elder, served one term each of two years. For the four years following 1875, Dr. Samuel Smith Purple was President, and for the six years from 1879 to 1884 Dr. Fordyce Barker was in office. For four years, 1885 to 1888, inclusive, Dr. A. Jacobi was President, and from 1889 to 1892, inclusive, Dr. Alfred L. Loomis directed the affairs of the Academy. For the next sixteen years, to 1909, the Presiding Officer has served only a single term of two years.

The presidency of the New York Academy of Medicine is, in my opinion, an office second to none in importance in medical affairs in the United States. While the great national organization—the American Medical Association—covers a wider field and deals in large measure with the most important scientific and technical problems in medicine, and is working with equal zeal for the advancement of the profession and for the cause of humanity, it also deals largely with public affairs and with what we must of necessity term "medical politics," and in this respect occupies a field entirely apart from the Academy, which stands solely for medicine in its scientific aspect.

From the day of its foundation the Academy of Medicine has advanced steadily in the one fixed purpose—to become a center for scientific medicine, where the great discoveries which medical research is constantly making, and where the results of a world-wide experience in the prevention and treatment of disease and injury may be first announced to its Fellows and the profession, and through these to the world at large.

It is, therefore, essential that the Presiding Officer should keep closely in touch with all that is progressive in our science and art and strive to give it expression from the rostrum of the Academy.

There has been found no difficulty in securing for our meetings the leading men in medicine, not only from our own country, but from all parts of the civilized world. It is a fitting recognition of the Academy's position that such men as our distinguished guest on this occasion, the President of the American Medical Association, deem it a privilege to give to the profession, through its members, the results of their labors.

Among the symposia which attracted more than ordinary interest was that on Typhoid Fever on March 7, 1907, when there were submitted detailed reports of the fatal epidemics which swept over Pittsburg, Scranton, and Berwick, Pa., in 1906. These papers were contributed by Dr. J. J. Bowman, of Berwick; J. F. Edwards, Superintendent of the Bureau of Health, Pittsburg, and Dr. J. M. Wainwright, of Scranton, Pa. The interest in this meeting was further emphasized by a contribution of their researches in "The Bacteriology of the Blood in Typhoid Fever, Based on an Analysis of 1,600 Cases," by Doctors Warren Coleman and B. H. Buxton, of New York City.

On March 21, 1907, Dr. F. S. Mandlebaum, pathologist of Mt. Sinai Hospital, read a paper which deserves to become classical, on "New Growths of the Bladder," based upon researches carried on for a long period of years in the medical laboratory of that great institution.

*Delivered January 5, 1911.

The Carpenter Lecture for 1907, by Dr. Edward A. Ayers, upon "The Mosquito as a Sanitary Problem," was of great interest, and on November 7, 1907, there was first announced from the forum of the Academy of Medicine a report on the "Serum Treatment of Epidemic Cerebro-Spinal Meningitis," by Doctors Simon Flexner and J. W. Jobling, one of the most important and original contributions from Fellows of the Academy to the science of medicine within the last decade. There followed this announcement a report on "The Recent Epidemic of Poliomyelitis," by Doctors Virgil P. Gibney, Charlton Wallace, and L. Emmett Holt.

At the Anniversary Meeting on November 29, 1907, "The Sanitation of the Canal Zone," with stereopticon illustrations, was the subject by Col. W. C. Gorgas, M.D., U. S. A., since then made an Honorary Fellow of the New York Academy of Medicine. The demonstration made at that time on the conquest of the tropics for the white race, as determined by the great and successful work of this distinguished physician, was as gratifying as it was instructive.

At the meeting of the Section on Pediatrics on January 2, 1908, we were honored by the presence as lecturer of Drs. John McCrae, of Montreal; S. McHamill, of Philadelphia, and J. Lovett Morse, of Boston; and on February 6, 1908, we listened to an instructive and interesting address by Dr. Edward Reynolds, of Boston.

On April 16 of that year (1908) there was submitted to the Academy a paper on "The Pathological Changes in the Thyroid Gland as Related to the Varying Symptoms in Graves' Disease, Based upon the Pathologic Findings in 275 Cases of Exophthalmic Goiter," by Dr. Louis B. Wilson, of Rochester, Minn., and at this meeting there were contributed classical papers by Doctors W. S. Halsted, of Baltimore, and Alfred Stengel, of Philadelphia.

The Wesley M. Carpenter lecture on October 8, 1908, on "Some Phases of the Evolution of Modern Preventive Medicine as Illustrated by the Present Campaign against Tuberculosis," was delivered by the distinguished Dr. German Sims Woodhead, Professor of Pathology in the University of Cambridge.

On November 5, 1908, "The Surgery of the Bile Passages" was the subject, at which meeting a paper of extraordinary value by Dr. John C. Munro, of Boston, was read.

At the Anniversary Meeting of that year—on November 19—Major Charles Lynch, of the United States Army, who represented our Government during the war between Russia and Japan, gave an illustrated address upon "Medical Service in a Modern Army in War as Exemplified by the Japanese Army in the Russo-Japanese War."

On December 17, Dr. B. Merrill Ricketts, of Cincinnati, contributed an interesting paper, and on January 21, 1909, in a symposium on "Cancer of the Breast," two distinguished surgeons, Drs. W. L. Rodman, of Philadelphia, and Maurice H. Richardson, of Boston, were guests of the Academy and read papers upon this subject.

On March 18, 1909, a paper entitled "What Becomes of Our Cripples?" was read by the eminent physician, Dr. de Forest Willard, of Philadelphia, who within the last few weeks, to the grief of all who love and respect a great and good man, has gone "to the undiscovered country, from whose bourn no traveler returns."

On May 6, 1909, there was a symposium on "Epilepsy," at which Drs. A. P. Ohlmacher, of Detroit, and E. E. Southard, of Boston, contributed a number of original researches made in the investigation of this disease.

On May 20, Dr. Chevalier Jackson, of Pittsburg, delivered an address in the department of Laryngology, and on October 7, Drs. John B. Murphy and Chas. G. Stockton contributed instructive papers on Gastric Ulcer.

On October 21, 1909, the Wesley M. Carpenter lecture on "Some Aspects of Rocky Mountain Spotted (Tick) Fever as Shown by Recent Investigations," was given by Dr. Howard T. Ricketts, Professor of Pathology in the University of Chicago, who in his devotion to science and humanity sacrificed his life by an infection of typhus fever while studying this dreadful malady in a foreign land.

At the Anniversary Meeting on November 18 of that year Dr. Louis Livingston Seaman delivered a most interesting lecture on "Personal Obesrvations of the Sleeping Sickness in Uganda."

On December 2, 1909, Doctors Edward Martin, Professor of Surgery in the University of Pennsylvania, and Robert Le Conte, of the Medical Faculty of that great institution, delivered addresses before the Academy on "The Surgical and Medical Aspects of Affections of the Colon," and on December 16, for the first time in New York City, there was a symposium on "Pellagra," at which Doctors J. W. Babcock, Superintendent of the South Carolina State Hospital for the Insane, and J. J. Watson, a prominent practitioner of South Carolina, made addresses, and there was exhibited a patient, brought to the Academy of Medicine from the far South, as a practical illustration of the clinical history of Pellagra.

On January 6, 1910, Dr. George S. Derby, of Boston, read a most interesting paper on "The Best Methods for the Diagnosis and Treatment of Ocular Tuberculosis."

On January 20, 1910, Doctors Simon Flexner and Paul A. Lewis, of the Rockefeller Institute, submitted preliminary papers on "Experimental Poliomyelitis and Its Bearing on Epidemic Poliomyelitis in Man," to which was added an interesting address by Dr. Thomas Morgan Rotch, of Harvard University, on "The Conditions Pertaining to the Safeguarding of Early Life, from a Pediatric Point of View," which papers were discussed by Dr. David L. Edsall, of the University of Pennsylvania.

On February 17 there was contributed to the profession from the forum of the Academy the results of original researches of extraordinary value in two papers entitled "The Method of Respiration by Continuous Intratracheal Insufflation; Its Theoretical Significance and Its Practical Availability in Medicine and in Surgery, with a Demonstration," by Dr. S. J. Meltzer, and "On Experimental Intrathoracic Surgery by the Meltzer Method of Intratracheal Insufflation," by Dr. Alexis Carrel, both of the Rockefeller Institute. A third paper of great interest on the same subject by Dr. Willy Meyer and a demonstration by Dr. Charles A. Elsberg followed.

On March 3, 1910, there was a symposium on "Stricture of the Male Uretha," and a paper on the "Cause, Frequency, Pathology and Complications" was contributed by Dr. Hugh H. Young, of Baltimore.

On April 21, in a symposium on "Fractures at the Elbow," instructive addresses were made by two distinguished physicians, Dr. Oscar H. Allis and Dr. John B. Roberts, of Philadelphia.

On May 19, 1910, Dr. W. C. Stiles, of the United States Marine Hospital Service, read an interesting paper on "The Biology of the Hookworm, and the Importance of the Hookworm Disease from the Standpoint of the Northern Practitioner."

On October 6, 1910, "The Definition of Pernicious Anæmia and Its Treatment" was the subject of the evening, upon which occasion the Academy was honored by the presence of Dr. E. Grawitz, the distinguished Professor of Pathology in the University of Berlin.

On October 20 Major F. F. Russell, of the United States Army, delivered the Wesley M. Carpenter address on "The Control of Typhoid Fever in the Army by Means of Vaccination," a lecture which embodied an amount of original research work in connection with the control of this disease which justified the widespread interest that this subject aroused.

On November 3 the distinguished physician from Paris, Dr. Louis Wickham, delivered a most interesting lecture on "Radium and Its Application to the Treatment of Malignant Tumors," and on November 17, at the Anniversary Meeting, under the head of "Animal Experimentation in Medicine," there were delivered two notable addresses by the two eminent physicians, Doctors Wm. H. Welch, Professor of Pathology in the Johns Hopkins University, and W. B. Cannon, Professor of Physiology in Harvard Medical School.

On December 1, 1910, the attendance at a stated meeting of the Academy of Medicine reached its high water mark when 500 Fellows of the Academy listened to a symposium on "Hyperthyroidism," at which a paper on the surgical treatment of this disease was read by Dr. Charles H. Mayo, of Rochester, Minn.

On December 15, 1910, Dr. Barton Cooke Hirst, Professor of Obstetrics in the University of Pennsylvania, delivered an instructive address upon "The Clinical Peculiarities of Gonorrhea in the Child-Bearing Woman."

On December 29 there was a symposium on "Leprosy," at which nine cases of this disease were presented to the Academy for examination. Papers of great interest were contributed at the meeting by members of the Academy and by two distinguished visitors, Doctors Charles W. Duval and Isadore Dyer, Professors of Pathology and Dermatology, respectively, in Tulane University, New Orleans.

Within the last few years there has been added to the usefulness of the Academy a series of lectures which are intended to be not only of interest to the profession but educational to the laity.

In my opinion the Academy of Medicine should stand for more than the strictly scientific forum of the medical profession of Greater New York, for, without interfering in the least with its scientific work, it can be made the center of distribution for information of value to the public concerning the health and welfare of the community.

These public lectures have been largely attended, exciting great interest, as they have dealt with such problems as the "Public Milk Supply," by Doctors Rowland G. Freeman and Thomas Darlington, and Mr. William H. Allen; "Possible Progressive Growth in Muscular Efficiency after Fifty Years of Life without Systematic Physical Exercise," by Mr. Horace Fletcher; "Observations on the Results of Tests for Physical Endurance at the Yale University Gymnasium," by Prof. W. G. Anderson; "Some of the Triumphs of Scientific Medicine in Peace and War in Foreign Lands, with Suggestions upon the Necessity of Important Changes in the Medical Service of the United States Army," by Dr. Louis Livingston Seaman; "Medical Expert Testimony," by ex-Judge Rufus B. Cowing; "The Character, Status, and Economic Value of a National Department of Public Health," by Dr. Charles A. L. Reed of Cincinnati, chairman of the National Committee on Medical Legislation; "The Need of New York State for Better Vital Statistics in Its Campaign against Tuberculosis," by Prof. Walter F. Wilcox, Cornell University; and in addition to these public lectures, which fall upon the fifth Thursday of every Academy month, the Council and the Trustees have opened their doors to such associations as the Public Health Education Committee, working with gratifying success in attracting large public audiences for the dissemination of special instruction.

In formulating the programs I have endeavored to divide them as evenly as possible between the members and those not members. As there are twelve sections or subdivisions of our work, and as the average number of stated meetings of the full Academy in Hosack Hall is eighteen each year, under this plan of an equal division between the Fellows and the outside profession it is impossible for each section to have one stated meeting a year. Although this may seem a hardship, the results for the last four years are, in my opinion, such as to justify a continuance of the policy.

For 1907 the attendance at these stated meetings amounted to 1,800, the average being 112. In 1908 the average rose to 122. In 1909 the stated meetings attracted an attendance of 2,050 members, the average being 137, and in 1910 the attendance reached the unprecedented number of 2,680, an average of 157, the excess of 1910 over 1907 being 880.

A matter worthy of most serious consideration by the Academy relates to the sections, and especially to the choice of a chairman and secretary for each. Officers in charge of these separate departments of the Academy's work should be selected not only on account of their high scientific attainment, but they should also possess tact, energy, and executive ability.

While not unmindful of the force of the old maxim that "comparisons are odious," in order to emphasize what I have just said, and in the hope that it may benefit the Academy hereafter, let me cite to you the report of some of the sections for the last four years: While the Section on Public Health in 1908 had an average attendance of only 30, in 1910 it reached 171. In Pediatrics the average attendance in 1907 was 61, and in 1910 was 117.

An interesting feature of the management of this important department of the Academy for the last year was the inauguration of an interchange of meetings between the Pediatric Section of the New York Academy of Medicine and the Pediatric Society of Philadelphia, which attracted more than ordinary interest. The average attendance of the Section on Surgery rose from 50 in 1907 to 123 in 1910, while in the department of Neurology in 1910 it increased threefold over that for 1907. The publication of the attendance in the various sections during each official term is an important innovation. It creates a healthy rivalry and makes it possible for the Academy to know whether or not good work is being done.

The membership proper of the Academy is di-

vided, as you may know, into Fellows and Associate and Honorary Fellows.

On November 5, 1908, the constitution was amended, increasing the resident membership to 1,200 and on October 6, 1910, the non-resident membership was increased to 250.

The total resident membership at this date is 1,147, leaving 53 vacancies, which, with the list of candidates that have been recommended for fellowship by the Committee on Admissions, and with those now before the committee for consideration, will practically fill the list of resident membership. Of the non-resident Fellows there are now 151 members, making a total resident and non-resident membership in the Academy of 1,298. Within the last four years we have lost by resignation 33 members, by death 62, and there have been dropped for non-payment of dues 23—a total loss of 118. During this period (of four years) there have been admitted 338 new Fellows—a net gain of 220 in membership.

From the foregoing it is seen that there are practically no vacancies in the active resident membership, and in view of our restricted accommodations, which only a few years ago were ample and are now so insufficient and unsatisfactory, it is scarcely probable that the Council and the Committee on Admissions will recommend to the Fellows a further increase in the membership limit until we can provide more room.

Every member of the Academy should feel a just pride in its great library. It is not only the most valuable collection of medical books and periodicals in the United States, with the one exception of that belonging to the Government at Washington, but it is recognized as the medical department of the Library of Greater New York, whose magnificent building adorns our principal avenue in the heart of the metropolis and is only a stone's throw away.

There are in our shelves 84,820 bound volumes and 46,000 unbound publications. Our list of periodicals, weekly and monthly, printed in every civilized language, amounts to 1,520.

In replenishing this library between $9,000 and $10,000 is expended annually. We have been greatly indebted within a recent period for important donations of books and of money to this division of our work.

During the past year the Mott Memorial Library of 3,000 volumes was given to the Academy, and among private donations that of Dr. Edward P. Fowler of 1,000 volumes and of Dr. George M. Lefferts of 400 volumes and other generous gifts have added to its value. Donations of books, journals, and pamphlets are being constantly received, and if all the Fellows and members of the profession would bear in mind how useful books which seem so old as to be out of date are to a library such as ours, they would contribute such material to the Academy. For 1909 the special endowment fund of the library amounted to $68,894.94. In 1910, by the will of Mrs. Landon Carter Gray, as a memorial to her husband, a late Fellow of the Academy, $50,000 has been added to this endowment, making a total of $118,894.94, the income from which will be applied to the maintenance of the Library Department.

You are well aware of the fact that this active feature of the Academy's work has in late years become overcrowded with material and with visitors, and what is true of the library is true also of Hosack Hall and our Section Rooms, which can no longer comfortably accommodate our audiences. At some of the recent stated meetings in this hall every chair in the amphitheater has been taken, the grill room filled, and every seat that could be placed in the gallery has been taken—and even then, to our embarrassment, a great many physicians attending have been compelled to remain standing during the entire scientific session.

Foreseeing this, the Council and the Trustees two years ago took the first step toward increasing our facilities by directing the Library Committee to set forth in a report the present condition and the future needs of the library. Their report, made on November 24, 1909, explicit, satisfactory, and convincing, was submitted to the Trustees on July 1, 1910, approved, and submitted on July 18 to a special meeting of the Academy, at which it was determined to purchase for $220,000 the lot on Forty-third street immediately adjoining our present holdings on the east and the lot extending back from that point to Forty-fourth street. This has been done, and while a preexisting lease on the property 15 West Forty-third street may prevent our possession for the next few years, we have already occupied the purchase on Forty-fourth street, which communicates with the present library quarters, and have relieved in considerable measure the pressure upon our stack-rooms by transferring from it 30,000 volumes of books less frequently called for by our members.

At the same time the President was directed to appoint a Finance Committee to undertake the raising of money to pay for the new properties, and a Committee on Plan and Scope to consider and report to the Trustees for their final approval changes or structural additions which may be found necessary. These committees are working assiduously, and it is gratifying to be able to report that already 54 Fellows have either paid $1,000 in cash or signed an obligation to pay this amount at the rate of $200 a year for five years, and others for smaller sums, amounting in all at this date to approximately $67,000.

When we take into consideration the fact that the Finance Committee has been organized and at work only a few weeks, the result of their tact and industry is evident. No less evident is the demonstration of pride in and unselfish devotion to the best interests of the Academy, in the generosity of its Fellows who have so liberally contributed to its advancement.

While the devotion and loyalty of its members are its most valuable and lasting assets, the Academy is not without material wealth. Stated concisely, it is as follows:

Lots occupied by the present building	$375,000
Recent purchases at price paid for in cash	220,000

This statement does not include endowments in possession of the Academy for special purposes, such as the Wesley M. Carpenter Lectureship Fund, the Alfred Lee Loomis Entertainment Fund, and the Edward N. Gibbs Memorial Prize Fund, etc.

The 1,300 members of this body, representing the most active and influential workers in the medical profession of New York City, are fully able to contribute from their own resources the $220,000 needed to pay for the new properties. With this demonstration of their faith, as shown by their works, they will not then appeal in vain to the generous laity of the metropolis for the money needed to build a new and greater Academy of Medicine—capacious, healthful, comfortable, and architecturally beautiful, a temple dedicated to the Science of Medicine and the welfare of mankind, a Mecca to which not only we, who are members, but every honorable physician and student may make his pilgrimage and feel at home.

INAUGURAL ADDRESS OF THE PRESIDENT OF THE NEW YORK ACADEMY OF MEDICINE.*

By WILLIAM MECKLENBURG POLK, M.D.,

Fellows of the Academy: It is easy for me to tell you how deeply I am gratified by your esteem and your confidence in giving to me this most distinguished position, and especially for your manner of bestowing it. If I take time to do it, out of the fullness of my heart my mouth would speak more words than our full program justifies. Taking to heart that excellent advice, to avoid the exploitation of self until the time comes to take off the armor, I pass at once to you and your work.

I wonder, as many of you pass to and fro from these halls, if you realize that you stand the foremost body of medical thought and opinion in the foremost city of the American Union. If necessary to prove it, one has to look merely at what these walls enclose and then learn of the problems constantly presented here to be discussed, and, if possible, solved. Look over the details of your organization, how it covers all phases of activity to which our calling compels us, and realize that, even outside this organization, your halls are yearly sought by allied activities as the place in which to discuss and strive at solutions of their problems.

You were organized January 6, 1847, for "the promotion and advance of Medicine, as a science and an art," which is to say for the investigation of medicine along natural lines, as distinct from speculative, including therein the discovery and development of preventing, correcting or arresting remedies. Some of these remedies to be unearthed in course of original investigations, some the outcome of human ingenuity in supplementing nature's wish or intent toward the conservation of our particular form or structure, or in combating, circumventing and even overcoming nature's hostile efforts toward crippling or destroying the individual, in part or in whole—the ways of science dominating the field throughout, the ways of art keeping in touch therewith.

When one remembers that the decade which witnessed your birth witnessed also the dawn of the science of bacteriology and the adoption of general anesthesia it is evident that you took up your work with the advent of the greatest lever ever given to medicine as a science and the greatest gift ever bestowed upon it as an art. You have grown in keeping with the extraordinary period in the life of our profession they created, for you have not neglected the opportunity to make good your purpose: "To aid in promoting and advancing medicine as a science and as an art."

Comparisons are not always disagreeable, even though sometimes they may be strained. I have often thought that for science in general, and especially for our science as well as art, this period was in truth a rebirth, and one which, in coming years, might equal in men's estimation the greatness even of the Renaissance of the Fourteenth and Fifteenth Centuries. And while it may be pleasing in this connection to dwell upon the comparative merits of the workers for the world progress of the two periods, we can hardly be counted presumptuous if we believe that from Pasteur, Darwin, Virchow, sprang discoveries and applications as far-reaching as those of Da Vinci, Campanella, Vesalius, and Sarpi.

Growing in such an atmosphere as the comparison suggests, it is evident your ideals could not rest short of the higher planes of science and art. To this end you realized that our entire profession must raise its level, and one of the brightest facts of your history is your never-ceasing effort to promote this. At all times your voice and influence have been aggressively used to secure the intellectual and educational equipment essential to those who enter upon the practice or the teaching of our profession. The response to this cry which has risen throughout the land is of deep import to us all, for upon its fruition depends the place our day and generation is to hold as custodian of our profession as a high and worthy pursuit. It is well enough to say that, there being all sorts and conditions of medical art, therefore there should be all sorts and conditions of artists, or, as one once said, "fifty-cent doctors and five-dollar doctors;" but the basis of our art being in reality science, and this branch of science dealing with life and its efficiency as developed chiefly in the human race, the sacredness of our trust compels at our hands the highest conceptions and the most skillful execution of such conceptions that human effort is capable of. But is there no place for such as seek to enter our ranks with less equipment of intellect and education than is here suggested? Yes! but just there we come to another aspect of this question—that of economics.

The first aspect is mainly ethical, bearing upon our obligation to our profession. The second relates to the status of the individual as a unit in the profession. As the larger number of us must use it as a means of livelihood, the grade of competition and the standards of the competitors have a direct bearing upon the manner in which this livelihood shall be gained. Here economics will supersede ethics. Have we not in this abundant reason to hold that your attitude upon the education of our members is essential to the good of the units, as well as that of the whole? Have we not reason to believe that the present overcrowding of our ranks is the direct outcome of ignoring or evading the demands for the better equipment of such as apply to enter? No doubt the institutions which conferred the degree, and the examining boards which tested and sifted the product, must share the responsibility for this state of affairs between them. Be this as it may, we have, and especially here in our city, more workers than can be properly provided for, and we must admit that, apart from the suffering among us which this engenders, medicine as a science, but more particularly as an art, suffers. When it entrusts itself to a superabundance of poor workmen the quality of the work deteriorates in spite of the fact that its

*Delivered January 5, 1911.

better workmen are themselves producing results which lift it up above anything ever before known. But they cannot do the work for all the people; their methods can but percolate downward, to be taken over for the larger part of the people by what amounts to, in far too many instances, unskilled labor. Unethical methods, unethical both as regards fellow-workers and the objects of the work, thereby obtain a vogue far too prevalent for the good of any or all concerned. Slipping farther and farther away from "Truth," the combination of insidious influences engendered under the cloak of that altruism which is our boast gather strength, blossom, and become rank commercialism. No longer confining its evil influence to the inferior class of workers, it sooner or later touches those even of the first rank; our art is therein exploited to its degradation. There are also signs that even our science, which is our very soul, is being bent to meet the commercial necessities of some scientists. We know that this science and art of ours is not alone in being thus subverted; but of all examples of such ill usage, the sinister aspect of the thing, because of the nature of our calling, stands out most prominently with us. It is time we realized this danger and understand that genius in discovery in science, and brilliancy in application of our art, should not serve as a cloak for the Charlatanism that may be associated therewith. There is nothing new in this, for, as just stated, not only our science but all sciences have ever been exposed to this danger. It is necessary, however, to take stock of the situation now and then and control it.

In the final analysis how few of us escape the taint. And here comes in the inestimable importance of the "Personal equation" in giving value to the utterances of those who essay to become leaders, whether as scientists or artists. The Academy is to be congratulated upon the watch it has placed upon this situation. It has kept itself a forum in which is offered free exposition and discussion, and while it has always reserved the place of honor for the saints it has recognized that, after all, the sinners should have a hearing, wisely counting them as sources out of which to recruit the ranks of the saints, recognizing therein a fundamental law of human society: that we must have sinners in order to grow saints. But the sinners must not lead.

Another cause for hearty self-congratulation is found in the action of so many of our leading hospitals in throwing open their wards to students. In this not only is the field of preparation for good workmen enlarged, but the additional work thereby entailed upon the attending as well as interne staff lends dignity to and increases the value to them of their duties, broadens their interest, and inevitably makes them more efficient in their work, thus increasing the importance of their services to the institution they serve. There is no question that the preceptorship system of half a century ago had a distinct value in the make-up of a student's education. This new system, bringing about a more direct and intimate association of teacher and student, perhaps has in it most of the latent good in the preceptorship, and even more, in that the intimate influence is brought to bear upon minds in a measure not only trained but already informed upon the subject taught. While all this is not to be set down to your sole credit, yet no one can deny that the stand you take upon the entire subject of medical education has, after years of effort on the part of those primarily interested in this branch of education, made easier the fulfillment of practical ideals.

And now I ask your indulgence that I may present to you certain ideas upon the general subject of hospital work, which as a part of the machinery of medicine must touch you in the future—perhaps in the near future. From time to time a voice has been heard in protest against the multiplication of hospitals; various reasons were given for the protest, but it is not necessary to repeat them now. The most potent antagonistic influence was of necessity the item "means of support," not medical, but material support. Granting that a hospital is always in place, the question has been asked, "Do our hospitals perform their full function?" Is that function limited to providing beds for sick people, with an out-patient department conducted mainly as a feeder to those beds? Is it not possible, through its out-patient department, for instance, to organize and conduct a movement for the purpose of teaching people and proving to them the value of their own beds? There was a time when the teachings of bacteriology could only be fulfilled in a hospital, the item of expense to the individual being a powerful argument in the hospital's favor. Pushing germ contamination to its utmost, and properly so, too, in its period of trial and development, the anti-hospital prejudice was greatly overcome, until it appears to some observers that the bed at home is no longer other than a resting place for the strong and well; the ailing were to be cared for at the hospital. In other words, cannot something be done or planned through which hospitals can extend their grade of work to the homes of the poor, instead of using all their resources toward increasing the number of their own beds. Throughout this city are already at work systems of "social service," designed, and, so far as I know, confined to the helping of such people as have not the means to help themselves. Most of the visitors are women of some education, usually trained in fact, some as sick nurses, some on lines of domestic economy. Cannot some form of co-operation between one or more of such organizations, on the one hand, and the hospital outlying services and the independent dispensaries, on the other, be effected, extending the latter beyond the mere dispensary care of a patient to the care within the home. The detail of such work can be readily worked out, in fact has been largely worked out in the Massachusetts General Hospital, and, I am sure, at no great additional expense—additional to that incurred by the hospital work (intra or extramural), on the one hand, and the social on the other. I believe such a system would be more effectually administered from the hospital, as a center, by merely extending the scope and activity of its out-patient department, it being enforced that only such people as under the law the out-patient department is competent to care for are to get it in their own homes—such as have not and cannot employ medical care of themselves. A rich product of such a system is the insight afforded of the living condition of a large circle of people, an insight bearing more or less directly upon the relations existing between such people and the profession outside the hospital force.

It seems to me the time has approached for us to begin a more rigid demarcation of the lines which should be drawn between institutional relief of the sick and home relief. The State and community undertake to cover both, in the one case providing and maintaining buildings equipped for the purpose of institutional relief, in the other enacting laws,

and constructing the machinery for their enforcement, to provide and maintain sanitary dwellings and places of work for the less prosperous members of society. Owing to evasions of the tenement house and health laws, the homes of such people are less attractive than they may be; the hospital situation, developed to a high state of efficiency, presents just the opposite picture; hence the steadily increasing flow of people out of the homes into the wards. Institutionalism is steadily dominating the home, and with it goes its allied influence, communityism, which, rightly interpreted, means communityism versus individualism. If communityism is preferable, there is no need of any line of demarcation; if individualism, the time for the demarcation has come. If our hospitals are to enter this field upon the side of individualism, and there are many reasons why they should, the same self-restraint as to the objects of their work must exist as the State now requires of them in dealing with applicants at their dispensaries. If through proper co-operation with social relief forces already at work even a few families in each sub-district can be aided to successfully face at home their problems of disease, the influence upon others about them wishing to live on similar lines must be stimulating and thus aid in stemming the rush toward institutions. And these people, many of them able to command home treatment, ceasing to burden institutions, *would properly turn to such medical and surgical relief as dwells among them.* It would be a profitable study, an inquiry as to the part borne by philanthropy, and especially medical philanthropy, in furthering the effacement of individualism now going on, more or less, throughout the entire civilized world. City or town life has always and will always be inimical to its maintenance with the mass of people, and it seems that, especially in our city, individualism is being driven more and more into the corners; but I believe that the place it has held in the development of our type of civilization makes it well worth contending for. Therefore any movement tending to this end is worthy of our consideration and support. While dwelling upon the many phases of this subject, it has occurred to me that one of them was much more our own than is implied in the general consideration of it just presented. At one time among us were a large and influential class of practitioners known as the general practitioner. From these were recruited what was known as the Family Physician or House Doctor. He has largely disappeared from the home life of the better conditioned people of our cities, and in all walks of life his position and influence have been undermined—less so in rural districts than urban. We therefore no longer have among us a type of man who, because of his intimate relations with the family life of his patrons, had the human side of his character expanded, and in a great many instances fine types of professional excellence were thus produced. It would be an excellent thing for us if this type could be fostered; that he will be preserved I believe, seeing that already conditions which submerged him are being readjusted upon a footing favorable to his reappearance.

Gathering up the threads of my discourse, they unite to emphasize the strength and importance of your position in this community. Realizing it, you will continue in all your relations to fashion yourself in the future as in the past upon that most "unbendable, incompliable, firm, and adamantine thing in all the world—TRUTH."

TRANSFUSION OF BLOOD IN THREE CASES OF PERNICIOUS ANEMIA.

By DAVID BOVAIRD, Jr., M.D.,

NEW YORK.

"Transfusion of blood from a healthy individual to a patient with pernicious anemia," writes Cabot in Osler's *Modern Medicine,* Vol. iv., p. 636, "is not to be recommended and should not be done."

Some experience of the beneficial effect of transfusions in a patient suffering from malignant endocarditis had, however, impressed upon the writer the value of an influx of healthy blood to a patient suffering from a chronic poisoning. The experiment has, therefore, been tried on three patients suffering from pernicious anemia during the past year, with results of such importance as to lead to their publication.

Case I.—Male, 54 years of age; single. The family and previous personal history were good. The patient could remember no illness before the onset of the present. No venereal infection. For 15 or 20 years he had used alcohol and tobacco to excess. Present illness began two years ago with nervousness, insomnia, and some weakness. For the past year he has been jaundiced at times but without pain. For one year he has had a slight cough. In January last his feet began to swell and the swelling gradually extended upward till hands and face were affected. He has been in bed for seven weeks. For one week during this time he vomited blood daily. At the same time he was very yellow and skin was tense. One and a half quarts of fluid were drawn off from the right pleural cavity. The jaundice and edema have gradually passed off. Recently he has been short of breath, with increasing weakness, pallor, and headache.

Physical examination on admission. The patient is a thin, cachectic, anxious-looking man, greatly depressed mentally. The skin is dry and somewhat lemon colored. He suffers from some dyspnea but without cyanosis. The conjunctivæ are exceedingly pale, the scleræ slightly icteroid; the pupils normal. The ears are normal. The teeth are in fair condition, the tongue rather dry and somewhat coated. The tonsils and pharynx congested. The mucous membranes are all exceedingly pale. The lymph nodes are normal. The heart enlarged downward and to the left; both presystolic and systolic murmurs heard at the apex. The presystolic is limited to the apex, the systolic transmitted to the left axilla. A soft systolic blow is heard over the pulmonic valve. The pulses are equal, regular, and of moderate tension; rate 92. Liver dulness extended from the fifth space to a point 10 c.m. below costal margin in the nipple line. The edge was readily palpable, smooth, not tender. Spleen was apparently normal. Abdomen otherwise normal. Genitals normal. Extremities wasted but free from edema. The urine was of normal quantity and specific gravity with a trace of albumin and at times hyalin casts. The urine also showed a trace of bile, but no indican. The feces showed no parasites or ova. The blood examinations indicated a pernicious anemia. The cardiac changes were regarded as probably due to an old and well-compensated valvular lesion. The enlargement of the liver was accounted for by the protracted alcoholic habit.

The patient was so lethargic that it was difficult to feed him. Iron and arsenic were ordered but had to be stopped in a few days because of nausea. Day by day the patient became paler, more

* Transfusion April 24th.

stupid, and more dyspneic, till it seemed as though he must surely die unless helped by some vigorous measure. He was finally confined to bed and apparently moribund. At this juncture a transfusion was determined upon and arranged for by his friends, the patient being by that time almost comatose and quite incapable of discussing the subject for himself. A young and vigorous man, fresh from the plains of Texas, was found to fill the part of the donor, and the transfusion was done on April 25 by Dr. Eliot. The immediate effect of the transfusion was impressive. The color could be seen slowly gathering in the apparently bloodless lips and cheeks, which from chalky pallor quickly changed to healthy red. Even on the operating table the patient roused and began to speak readily and naturally. The following day he was found sitting up in bed looking very comfortable, and greeted his physician with the query as to when he might go for a walk! From that day on his progress was steadily upward. The hemoglobin had mounted from 25 per cent. to 50 per cent. during the transfusion. Five days afterward the hemoglobin was 60 per cent. and it mounted steadily to 85 per cent. on May 31. The general condition of the patient improved in like manner. His appetite returned; he digested his food well. He was soon allowed out of bed and spent much of his time out of doors. The records of the blood examinations are here given.

From the hospital the patient went to Delaware Water Gap, where he continued to gain. He ate well, felt well, and walked from six to eight miles a day. This condition continued till the end of July, when he began to lose his appetite, and since then he gradually became weaker and paler. About September 1 he became jaundiced and was sick for two days with nausea and vomiting. Soon afterward he suffered a severe fall and was unable to rest or sleep from pain in the left hip and side. He failed steadily and returned to the hospital October 23, in much the same condition as he had entered in April. The physical examination was practically the same as that given above, except that the patient was brighter, a little less anemic, and appeared to still have some energy. Examinations of the urine and feces resulted as before. From the time of his admission the patient failed steadily despite our best efforts by feeding, medicines, fresh air, and sunshine to stop the progress of his disease.

A table of examinations made at this time follows:

Date	November 1	November 17	November 26	November 26†

† Second count.

As all other efforts failed a second transfusion was proposed, assented to, and the effort to secure a donor instituted. Meanwhile the patient gradually passed into a state of extreme anemia, with lethargy, anorexia, insomnia, and depression as shown before. Then suddenly, without apparent cause, he began to mend. The blood picture within a week changed so remarkably that the staff examiner, who had been making all the examinations, thought the transfusion had been done without his

knowledge. Coincidently the general condition changed accordingly, the patient's appetite returned, he ate heartily, slept well, gained in strength, and again left the hospital on November 29, able to get about freely and enjoy being alive.

Case II.—Male, 59 years; married. In 1908 the patient had typical pernicious anemia. At that time he improved slowly but steadily under symptomatic treatment and at the end of several months resumed his occupation. He continued to work until May 27, 1910. For a year he had been troubled by swelling of the legs, dyspnea, and weakness, and ulcers had been gradually developing on various parts of his body, the legs especially.

The points of interest in the physical examination were the extreme anemia with well-preserved fat, edema of the ankles and legs, numerous ulcers over both legs. The urine and feces were negative. The blood showed 18 per cent. hemoglobin, 844,000 red cells; 3,500 white cells; monoblasts, megaloblasts, and the variations in shape, size, and staining characteristics of severe anemia.

The effort was again made by rest, careful feeding, fresh air, colonic irrigations, iron, and arsenic, to help him as on the previous occasion, but without success. The blood showed improvement for a time, but then failed again; the hemoglobin and red cells standing on September 8 practically where they were at the outset. On September 16 the red cells numbered 1,080,000; the hemoglobin 18 per cent.; the white blood cells 7,200. A transfusion was determined upon, but great difficulty was experienced in finding a suitable donor. Two applicants were tried but rejected because hemolysis resulted from the admixture of their blood with that of the patient. A suitable donor having finally been found Dr. Woolsey attempted to effect the transfusion by joining vein to vein (median-basilic) but finding that the pressure in the patient's vein was higher than that of the donor was obliged to give up the method. The donor then refused to have an artery used to replace the vein and we were forced to begin anew. Another donor was finally found, who proved satisfactory on physical examination, and whose blood was suitable. The transfusion was then done by Dr. Woolsey on September 26. The union of vein and artery was made satisfactorily but the exchange of blood had to be stopped on account of faintness of the donor when the patient's hemoglobin had reached 35 per cent. Immediately after the operation the patient's temperature began to rise and mounted steadily to 106°. On the following day, the patient breathed with much difficulty, became dull, and then comatose. The face and eyelids became swollen and puffy, and the trunk and extremities were covered everywhere by great blotches of eruption partly urticarial and partly hemorrhagic. At the same time it was discovered that the blood of the patient contained many malarial parasites, and that the same parasites were to be found in that of the donor! The donor insisted that he had never had malaria and that he was perfectly well at the time. Examination of the patient's blood showed no change in the hemoglobin, the urine showed no blood pigment, and we therefore concluded that no hemolysis had taken place, but that the phenomena described were in the nature of an anaphylactic reaction to the foreign serum. The bloods had been tested before the transfusion. These tests were repeated afterward and the two were shown to harmonize. The question of the possible influence of the malarial parasites was, of course, raised. The patient had no chill. The rise of temperature was a gradual ascension during 24 hours, the fall occupied three days, and there was no sweating. Quinine was given intramuscularly and by mouth. The parasites disappeared from the blood in four days and there were no later evidences of their presence or influence. For a time the patient professed to feel better and appeared to be somewhat benefited by the transfusion, but the hemoglobin steadily fell till on November 3 it had again reached 18 per cent. He had slowly become weaker, paler, more dyspneic, and finally succumbed on November 4. No autopsy was permitted. The case is reported not only as a failure of the method, but to point out a danger which we had overlooked, a latent malarial infection in a person apparently in perfect health. A search for malarial parasites in the donor's blood must now form part of the preliminary examination. There is little doubt that this latent malaria was the explanation of the quickly developed faintness of the donor, which interrupted the transfusion before the patient had received a sufficient quantity of blood to materially help him.

Case III.—Woman, aged 35 years; married. The family history was negative. Previous personal history of scarlet fever and diphtheria in childhood and pneumonia at seventeen. She was always sickly as a child. She had had no children, no miscarriages. She occasionally drank beer or whiskey, much tea, no coffee.

Present illness began one year ago with loss of appetite, frequent vomiting, and swelling of the legs. She knew no cause for her illness. Ever since she has been very pale and her legs have been swollen at times. Her menstruation has lasted but one or two days and has been very scanty. Lately her sight has been poor. She has not vomited recently, but food has oppressed her. Her appetite is always poor, the bowels regular, urination normal, sleep fair. She is very nervous.

Physical examination: Extreme, almost deathlike pallor, without marked emaciation. No dyspnea. Slight puffiness about eyes. Marked weakness and appearance of severe chronic illness. Ears: normal. Eyes: Conjunctivæ, extremely pale; pupils normal. Teeth: Upper set entirely gone, a few in lower jaw. Tongue and mucous membranes extremely pale. Throat, pale; subcutaneous lymph nodes, not palpable. Skin very white, otherwise normal. Neck and thorax, normal.

Heart: Apex impulse visible and palpable in fifth space, 9 cm. to left. Left limit of dullness, 10 cm. to left midsternal line. Right border beneath sternum. Over the heart is heard a soft, blowing systolic murmur transmitted into left axilla, while along the left sternal margin and in the third and fourth spaces is heard a faint murmur, diastolic at times. The aortic sounds are very faint, no murmurs, no accentuation.

Pulses are small, equal, regular, correspond to apex, soft; rate 90, the wall of artery not felt. Lungs: normal. Liver, not palpable; dullness, normal. Spleen, not palpable. Abdomen, normal. Extremities, upper normal, except for pallor; lower, puffy, without edema. Knee jerks, sluggish; other reflexes, normal.

On admission the hemoglobin was 10 per cent.; red blood cells, 700,000. The urine amounted to 30 ounces, sp. gr. 1.013, a faint trace of albumin, many hyalin and granular casts. A later examination showed no casts. The feces showed no ova, no parasites. Bacteriologically the stools showed no marked divergence from normal. The patient was

extremely lethargic, and day by day became more stuporous till she was difficult to rouse. She took very little nourishment, and it appeared certain that she could live but a few days. The temperature ranged from 99° to 102°. Under these conditions transfusion was decided upon as the only means of giving her a chance for life. The first donor's blood proved incompatible, but a second with an harmonious blood was secured.

The transfusion was done by Dr. Woolsey September 29.

At the time of the operation the patient's hemoglobin registered 13 per cent.; at the end of the transfusion, 45 per cent.

The improvement in color and general condition was immediate. The following day she was apparently much better, although rather irrational. Forty-eight hours after the transfusion the patient's condition became worse. The mind became more clouded and she became noisy. The pulse was weak, the face puffy, the conjunctiva slightly icteroid, there were many râles in the lungs, and much mucus in the throat. Under stimulation she rallied and proceeded to make a rapid recovery. The temperature after ten days became normal, the mind became clear, the blood improved, and with it the patient's vigor. By October 17 she was able to begin walking, and on November 6 she was sent home in excellent condition with over 80 per cent. hemoglobin and 4,104,000 red cells. One month later she was still in excellent condition, able to get about and lead her usual life.

This patient was last seen January 10, 1911. The report of the blood examination at this time is included in the accompanying table. She appeared to be in good health, reported herself as feeling well, enjoying a good appetite, sleeping well, and so vigorous that she expects to resume her usual household duties.

Of these three patients with pernicious anemia upon whom transfusion has been tried, two have benefited to the extent of prolonging their lives for months; in the other patient the benefit was so slight and transitory as to amount to nothing. The question naturally arises whether the conditions dealt with were true pernicious anemia. In the first case the suspicion may arise that we were dealing only with a profound anemia secondary to the hematemesis reported. The hematemesis was limited to one week, and the anemia had become progressively worse after its cessation, and despite efforts to improve the patient's condition. The absence of carcinoma or parasitic infection has been assured both by the clinical course of the disease and repeated examinations. The blood picture with its extreme paucity of red cells, high color index, megaloblasts, normoblasts, together with the stippling and the variability in the size, shape, and staining of the red cells may be termed typical. Ehrlich's view that the prevalence of megaloblastic forms in the blood is essential to the diagnosis of pernicious anemia has not been borne out.

In a recent number of the MEDICAL RECORD (October 29, 1910) Grawitz points out that macrocytosis is not so characteristic of this condition as microcytosis, and that indeed there is no constant blood formula. But whatever doubt might be entertained as to the diagnosis should be satisfied by the observations made on the occasion of the patient's return to the hospital in the fall. The sudden change from a grave condition to one of comparative safety, accompanied by the remarkable "normoblastic crisis," belongs to no other disease.

In the second case the diagnosis will hardly be questioned. Our experience with this patient, however, brought out forcibly some of the difficulties which beset transfusion. After the expediency of transfusion had been determined more than a month elapsed before a donor of any kind could be obtained. In this city appeal to various agencies having to do with the unemployed usually brings one or more candidates in a short time, but as it chanced to be midsummer, few men were looking for aid and apparently none of these cared to earn the fee offered for such service. When finally candidates did present themselves two had to be rejected because of incompatibility of their blood with that of the patient. A suitable donor having finally been secured, the procedure failed by reason of the attempt to use the vein-to-vein transfer instead of artery to vein. Transfusion having finally been accomplished from a fourth donor, the process had to be stopped by reason of faintness on the part of the donor, and the discovery was made that the donor had a latent malaria, although apparently in perfect health, and that the patient's blood also con-

* Transfusion September 29th.

tained malarial parasites. Although the prompt administration of quinine destroyed the parasites and prevented any ill result from their presence, the malarial infection was of considerable importance as doubtless determining the faintness of the donor and the early cessation of the transfusion.

The severe anaphylactic reaction which followed the transfusion in this case was also noteworthy. The third patient also experienced a reaction, but of much less degree. Tests of the blood, both before and after the transfusion in the second case, would appear to result from the introduction of a large quantity of foreign serum and to concern the tissues of the body, especially the lungs and skin, rather than the blood itself. The violence of the reaction in the second patient threatened his life. In the third patient the reaction was not quite so severe.

The third patient was a woman of 35 years. The absence of any sufficient cause for so grave an anemia, the clinical picture, and the blood findings established the diagnosis of pernicious anemia as firmly as is possible under the conditions.

Results of transfusion: 1. Immediate. The transfusion after union of the vessels occupies an hour or more, as a rule. During that time the appearance of death-like pallor which these patients present changes to that of comparative health. The color first reappears in the cheeks and tongue and then mounts in the lips, the conjunctivæ, and the skin generally. The hemoglobin can easily be followed, and in a Dare's or Fleischl's instrument shows a steadily increasing percentage. In the two favorable cases this amounted to an increase of three or four times the original percentage. There is a corresponding change in the patient's mental condition and vitality, which seems, in patients so near to death, almost miraculous. This was strikingly true in the first case.

2. Secondary. In both the favorable cases the transfusion introduced a period of improvement which in the first case has now lasted nine months, in the third, two. The hemoglobin and the number of red cells have increased steadily until 80 per cent. and more has been attained.

The general vigor and well-being have been correspondingly improved. The relapse and recovery observed in the first patient show clearly that equally remarkable improvement may be observed without transfusion, yet when the hemoglobin falls below 20 per cent. and the patient becomes comatose waiting for natural recovery regularly proves vain.

How long the improvement secured in our two patients will continue no one can say. The disease is, of course, not cured, and relapse with its usual outcome is to be expected.

Our experience seems to indicate that as a last resort transfusion in pernicious anemia offers the possibility not only of averting death, but for a time at least restoring the patient to comparative health and comfort and initiating one of the periods of quiesence so characteristic of the disease.

Transfusion in this condition is fraught with perils of its own, first from immediate hemolysis of the new blood, secondly from the effect of the new serum such as occurred in two of our patients, an effect apparently in the nature of an anaphylactic reaction. The first danger can be avoided by careful preliminary studies of the two bloods, the safety of the red cells of both patient and donor being assured by testing them in the serum, each in that of the other. Whether a patient can be guarded against the possibility of a serum reaction by preliminary testing of his susceptibility to a small quantity, as may be done with diphtheria or other antitoxic sera, is a question for future experience.

DIRECT INSPECTION OF THE RECTUM AND SIGMOID COLON.

By EDWIN BEER, M.D.,

NEW YORK.

Previous to 1895 the diagnosis of diseases of the upper rectum and sigmoid based on direct inspection was almost impossible. In that year Kelly gave the profession his set of tubes which marked the first step in our modern era. He tried to popularize this method of examination even though, as Tuttle* says, he neither invented the tube nor discovered the inflating power of atmospheric air. Pennington and Laws improved on the Kelly tubes by following in the lines indicated by Heuel. They made use of artificial inflation of the bowel. Tuttle also made use of this principle in his instrument. Strauss of Berlin subsequently modified these instruments, retaining the best features, and since six years I have been using an instrument constructed on the lines of Strauss, with some essential modifications.†

Despite the work of these and many other men it is surprising how much this field has been neglected by the general surgeon, to whom many patients come with diseases of the lower bowel. It is difficult to understand why such a simple method of examination, much simpler than cystoscopy, should have been treated so shabbily by the majority of the medical profession. In this field the pictures of disease are so clear cut that the observer, provided he has a fair pathological experience, can readily make positive diagnoses; moreover, the manipulation of the few necessary instruments is so simple that any one can readily acquire skill in their use. Nevertheless, in my experience, I find more men devoting themselves to cystoscopy, that much more difficult field, in which both the technique and the interpretation of the pictures are much more slowly acquired. In fact, I believe I have seen many more good cystoscopists among surgeons than well-trained proctosigmoidoscopists. Why this should be I fail to understand.

The importance of making accurate and early diagnosis, of excluding suspected neoplasms, can not be overestimated, and by direct inspection made with a good instrument we are now in a position to fulfill any such demands. In diseases of the lower bowel direct inspection is as important as it is in diseases of the larynx or in diseases of the bladder, kidneys, and urethra. Cases of diseases of the lower bowel ought to be regularly inspected, and the general surgeon ought to be able to make such an examination as well as the surgeon who specializes in proctology. When the internist realizes how simple, painless, and useful these examinations are I doubt not that he will do the work himself and make his own diagnoses without calling in outside aid.

Instruments.—The instrument‡ that I have made, and which I have used for six years with satisfaction, is very much like the Strauss instrument, and consequently owes much to the earlier instruments. The tube is 35 cm. long, each centimeter being

*Tuttle: "Diseases of the Anus, Rectum, and Pelvic Colon," p. 118.

†Presented in 1905 before the German Medical Society of New York City.

‡See cut representing sigmoidoscope, manufactured by Kny-Scheerer Co., of New York City.

marked off on its outer side up to 30. The ocular end is closed by a piece of plain glass fitted into the extension of the tube (light carrier) by an airtight bayonet hinge. The light carrier fits into the tube proper by a similar hinge and the light is close to the rectal end of the tube. By virtue of this double hinge the glass can be removed, leaving the lamp *in situ* and the applicators, forceps, etc., manipulated with the light burning. The caliber of the tube is smaller than that of the Kelly and many other instruments, and it can be used in most young patients (ten years old) as well as in adults. At the rectal end of the tube a rubber balloon is attached which can be distended to the requisite size, as required, by introducing air through one of the stopcocks near the ocular end from a graduated syringe. The object of this balloon is to produce local distention of the bowel at the point of inspection, and it is frequently very effective in doing so. It is of use chiefly in the sigmoid, as in the rectum distention is almost always adequate. When this balloon is distended air driven into the bowel from a hand bulb through the other stopcock frequently converts the sigmoid into a hollow viscus which is very rarely the case without the use of the balloon. Moreover, it is of great assistance as a local retractor straightening out the folds of the gut and exposing suspicious surfaces as well as in opening up the path which the tube must follow. I usually employ a finger cot or a finger of a thin rubber operating glove for the balloon, and usually use 75-100 c.cm. of air for its distention in adults. Before using the instrument I test the balloon and determine how much air is required to produce a distention of 3-3½ cm. (1¼-1½ inches) in diameter, or a circumference of about 10-12 cm. (4-5 inches). *In ulcerative conditions I naturally avoid distending the gut at all for fear of rupturing its wall.* I have had no mishap of any sort with this method, and have frequently been astounded by the assistance it has offered and by the extension of the field of vision which I have obtained by drawing the tube with distended balloon ¼-½ inch toward the anus while forcing air into the lumen of the gut. Any more extensive introduction or withdrawal of the tube with distended balloon is absolutely contraindicated. If such are carried out the balloon must be emptied preliminarily. After each use a fresh finger cot or finger must be applied to avoid carrying infection, as the rubber does not stand sterilization. Occasionally the balloon breaks *in situ* with an audible explosion. This shock, however, is so slight that no damage is done. Through the second stopcock, as stated above, air can be pumped slowly into the lumen of the bowel. This should be done without causing pain, and care should be taken not to overdistend the bowel. Usually the patient expels any excess alongside of the tube. Recently Foges has made a tube which is meant to open automatically externally, like a safety valve, to prevent overdistention. This is surely an unnecessary refinement.

The metal obturator is grooved so that when it is withdrawn from the tube no suction is created, air rushing in along these grooves. All applicators and forceps should be made with handles at right angles to the shafts, so as not to permit the hand to obstruct the view of the parts touched.

Technique.—The ordinary case I regularly examine in the knee-chest position, as it gives the most satisfactory exposure of the parts, and frequently allows of a complete examination without the use of any artificial distention either by injection of air into the lumen or by blowing up the balloon. Under exceptional circumstances, and under anesthesia, I use the Sims position. The instrument having been tested, its light regulated, and the balloon measured, 3-3½ cm. (1¼-1½ inches) in diameter, as above, and then emptied, it is introduced, thoroughly lubricated with vaseline, with obturator in place, through the sphincter. Then the obturator is removed, and the light carrier attached. With the light turned on the instrument is slowly pushed into the bowel, under the careful guidance of the eye, and not blindly, as is so regularly done with the tubes that are illuminated from without. The instrument must not be pushed with any force, but must follow the lumen of the bowel. Very frequently it will pass to the vault of the rectum and apparently there it sticks. No opening into the sigmoid is visible. Then, by drawing back and pumping air into the bowel, one will see the opening into the sigmoid at a lower level than the vault of the rectum, in its left lateral wall, as it allows some of the air egress in this direction. Having ascertained this important fact the beak of the tube is gently insinuated into the lower end of the sigmoid, and gradually introduced into the rest of the organ, careful examination being made of all its surface, both in going up and in retracing the steps. Often a complete examination may be made without pumping air into the gut or distending the balloon. If one has trouble in exposing the gut to view both methods of opening up the walls of the bowel are at hand and can readily be made use of. To get a good view of the bowel preliminary catharsis is not always necessary. In cases with diarrhea, *e.g.* in colitis cases, catharsis may be of no use in draining the bowel, and the operator will succeed in getting a better view by washing out the bowel with a long tube introduced through the sigmoidoscope. In the average case a cathartic on the day before examination, with an enema six to eight hours before examination, will usually give a clean field and insure a complete and ready inspection. Under exceptional

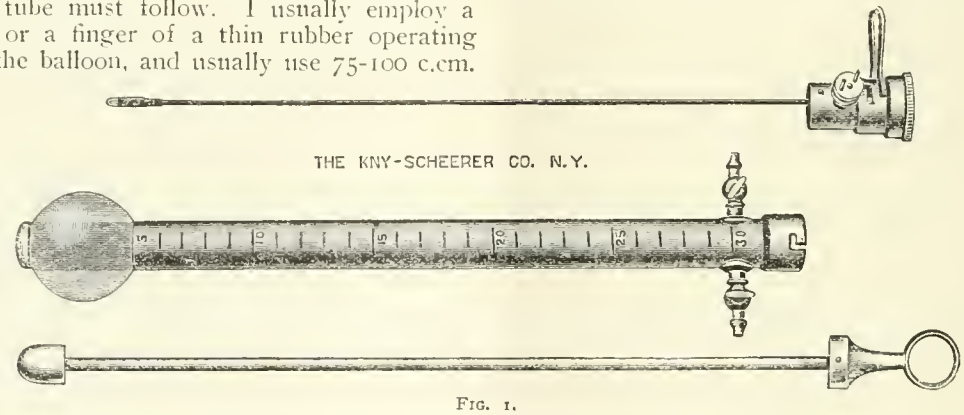

Fig. 1.

circumstances one may succeed in making a complete examination without any preparation at all, provided the patient's bowels have moved prior to the examination.

Inspection of the Anal Ring.—After examination of the upper bowel the tube should be withdrawn

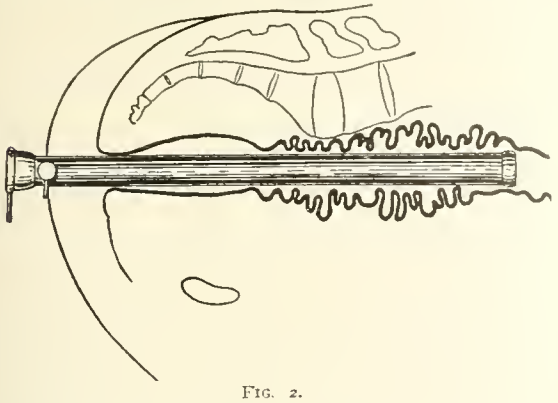

Fig. 2.

gradually, the inspection continuing all the time. When the irregular sphincteric ring is reached it should be carefully studied. In examining this (sphincteric) region, however, the tube is not as satisfactory as the fenestrated speculum or the heavy wire speculum. With a tube it is almost impossible to study the hemorrhoids that regularly occupy this area, whereas there is no difficulty in seeing them with any non-cylindrical speculum. Whether the cylindrical tube expresses blood from the diseased veins, as done by the tone of the sphincter, or whether it blocks the circulation's return from the skin area about the anus to the hemorrhoidal area, I do not know. *Experience has taught me never to exclude the diagnosis of hemorrhoids by inspection through a cylindrical tube.*

Localization of Lesions.—If lesions are discovered in the rectum their approximate distance from the anal ring is readily determined by reading the centimeter scale on the sigmoidoscope. However, as soon as the sigmoid is entered, approximately 11-12 cm. from the anus, we are more or less at sea in our localization, and are very liable to misinterpret our findings if we rely on our centimeter scale. A 30-cm. tube is sufficiently long to traverse the whole sigmoid. In other words, approximately 60 cm. of gut, under these circumstances, become folded on a tube of half that length. This process is well shown in the figure taken from Mummery* on the Sigmoidoscope (Fig. 2). With such extensive pleating of the gut on a straight tube it is evident that exact localization in these parts becomes difficult, if not impossible. Mummery has reported tumors above the middle of the sigmoid with 25 cm. of tube introduced, and at the middle of the sigmoid with 15 cm. of tube introduced. Others have had similar experience. I have seen with the tube introduced 20 cm. a tumor in the mid-sigmoid flexure which could easily be drawn out on the abdominal wall during the laparotomy for its removal.

Inspection of the Descending Colon.—The accompanying picture (Fig. 3), based on Strauss' and Foges' recent books, shows fairly accurately the relations that the proximal end of the tube may assume to the parietes. A tube of 30 cm. may at times, provided the descending colon has a mesentery, enter this part of the gut, but the examiner is unable to recognize the transition, though Schreiber describes a fold at this site. In very large patients a longer tube might under most favorable circumstances be used without colliding with the subdiaphragmatic organs, to go into the descending colon. For such purposes I have in readiness a 45 cm. tube similar to the one described above, but as yet have had no occasion to employ it. In the average adult in whom the 30 cm. tube passes readily the full length I should employ the longer tube provided there existed an adequate indication. If it passed beyond 30 cm. I should feel fairly certain that I was in the descending colon even though I could not detect the transition by any ocular signs.

Dangers.—That accidents may happen with long tubes in the bowel is self-evident, and consequently every examination must be made with great care. A number of patients have died as the result of inspection of the bowel, the tube piercing the wall of the gut and setting up a peritonitis. If no force is used and the end of the tube is guided by the eye, if no overdistention of the bowel is produced by pumping air into it, or into the balloon, if the observer cautions his patient against brusque movements, it is difficult to understand how any accident can occur, unless the bowel is already deeply ulcerated. In cases of this sort, in fact in all ulcerative conditions, no distention should be employed unless one is thoroughly experienced in this kind of examination. Moreover, frequently the less done in such cases the better. The slightest difficulty in introducing the tube from one point to another is a danger signal, and should induce the examiner to stop and retrace his steps. To make a diagnosis he need not study every ulcer and thus risk doing irretrievable damage.

Essential Symptoms of Cases Examined.—These symptoms are as follows: a, blood in stools; b, pus discharge in stools; c, diarrhea (obstinate); d, symptoms suggesting neoplasms; e, obstructive cases—constipation.

a. Blood in stools is undoubtedly one of the most frequent indications for inspection of the bowel, and if examination of the anal and sphincteric regions excludes these as sources of the blood we must look further. A great variety of pathological conditions in the upper bowel may produce this symptom, and

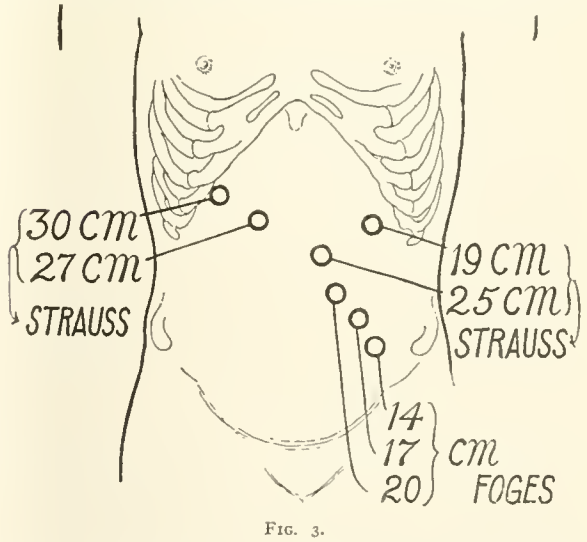

Fig. 3.

in this short sketch I naturally can not enumerate completely all of them. I shall refer only to some of the more interesting cases that have come under my care, to illustrate the value of inspection.

Case I.—Patient bleeding irregularly with stool and also between times. Anal and sphincteric

*Ballière, Tindall and Cox, London, 1906.

regions negative. At 8 cm. on posterior wall a distinct varicose vein was detected. Its mucosal covering was imperfect and bleeding was produced by the slightest touch with an applicator. Goldman (Freiburg) recently described these cases in some detail. Diagnosis: High internal varicosity or hemorrhoid.

Case II.—Patient bleeding. Distinct evidence of systemic lues. Inspection of bowel showed a typical bleeding, punched out ulcer at 13 cm. Diagnosis: Broken down gumma of lower sigmoid.

Case III.—Patient has frequent stools with blood and mucus. Inspection shows general hyperemia of the mucosa, with a very large number of superficial bleeding erosions. (This is a not uncommon pathological picture.) Diagnosis: Acute (erosive) catarrhal proctitis.

Case IV.—Patient has frequent stools with blood. Inspection shows general hyperemia of sigmoid, where numerous red superficial easily bleeding ulcers are detected. At 8 cm. from anus upward bowel shows granular thickened mucosa. Amebæ found in stool. Diagnosis: Subacute amebic colitis (sigmoiditis).

Case V.—Patient has frequent small stools with blood. Inspection shows the whole mucosa deep red in color, and studded with small polypoid projections of varying size which bleed very readily. Diagnosis: Polypoid proctitis and sigmoiditis.

b. Pus in stools:

Case I.—Patient passing considerable pus, blood, and mucus. Examination shows multiple small bleeding ulcers and extensive purulent membrane in which streptococci are found in large numbers. Diagnosis: Pseudomembranous ulcerative proctosigmoiditis.

Case II.—Patient passes irregularly moderate amounts of thick pus and complains of constant pains over sacrum. Inspection shows at 11 cm. an edematous hyperemic area on posterior wall, in the center of which is a fistula into which a probe can be readily passed to the sacrum, and through which small quantities of pus are seen discharging. Diagnosis: Abscess between sacrum and rectum perforating into bowel. Sacral osteoperiostitis?

c. Patients suffering from obstinate diarrhea:

Case I.—Patient has 3-5 stools each day, some colicky pain, and general malaise. Inspection of bowel shows in sigmoid a number of ulcers of fair size. As the patient has pulmonary tuberculosis the diagnosis of tubercular sigmoiditis suggests itself even though the bacilli were not recovered from the surface of the ulcers nor was the appearance of the ulcers quite typical.

Case II.—Patient has frequent stools for years. Had been proctoscoped and a polyp removed from the rectum. Inspection of bowel shows most extensive ulcerations of very irregular shape running down to the submucosa. A few shreds of hypertrophied mucous membrane run over the ulcerated areas, which communicate freely under these bridges. Here and there the mucous membrane shows polypoid growths. The disease is distinctly in the submucosa and the polypi are evidently the result of the chronic irritation, the whole making a typical picture. Diagnosis: Chronic amebic proctosigmoiditis (colitis?).

Case III.—Patient has attacks of diarrhea, occasionally blood and excessive mucus. Inspection shows extensive formation of polypi studding the mucosa of rectum and of sigmoid. No ulcers. Diagnosis: Polypoid proctosigmoiditis (colitis?).

d. In no class of cases is the examination of the bowel more satisfactory than in those in which the physician has suspected a neoplasm and the examiner can absolutely exclude the presence of such disease in rectum and sigmoid. On the other hand, the early diagnosis of neoplasms is possible only by means of inspection, and it is to be hoped that in the future all suspects will have the benefit of such an examination. In the diagnosis of tumor direct inspection of the bowel scores one of its most important triumphs.

Case I.—Patient has mildly obstructive symptoms and pains in rectum, with irregular discharge of blood. Inspection discovers a fair-sized polyp with long pedicle, and the suspected carcinoma is readily cured. Diagnosis: Polyp of upper rectum.

Case II.—Patient is suffering from lymphatic leukemia, and has an obstruction in sigmoid. Inspection shows at 14 cm. an almost complete obstruction of the bowel by large lymphoid nodules which project into its lumen. Some of these are blue, others deep red in color. The largest nodules are in size equal to a chestnut. Diagnosis: Leukemia infiltration of the sigmoid (perhaps abdominal Hodgkin's).

Case III.—Patient has occasional bleeding. Inspection shows three flat masses about 1 cm. in diameter in posterior wall of upper rectum. These masses are somewhat umbilicated and nonulcerated. Higher up there is a stellate scar. The picture was suggestive of syphilitic gummata, but the miscroscopic examination of a small bit of tissue made the diagnosis adenomata of rectum.

Case IV.—Patient has had frequent stools daily, of late, however, is constipated. Inspection shows at 11-12 cm. an ulcerated area with gelatinous yellow base, surrounded by raised tumefied masses of mucous membrane. The ulcerated area extended as a yellow band well up into the sigmoid. The picture suggested carcinoma, but a hypertrophic tuberculosis could not be excluded. A piece was removed for diagnosis, and the pathologist's report confirmed the suspicion of malignancy. Diagnosis: Adenocarcinoma of rectum.

Case V.—Patient had obstructive symptoms, but in view of the severe syphilis that he had suffered from the question arose as to whether his obstructive symptoms were due to a neoplasm or to syphilis. On inspection a hard resistance was felt with tip of sigmoidoscope at 14 cm., the highest level to which it could pass. Below this two hard ovoid nodules were detected in the submucosa, a picture seen at times in carcinoma cases, as the result of metastasis. Diagnosis: Carcinoma of sigmoid.

e. In obstructive cases and in chronic constipation inspection may be of great use. Previous cases illustrate this point very well in obstructive cases. In chronic constipation one usually sees little or nothing beyond perhaps an excessive dryness of the mucosa, though at times one does note an excessive development of the rectal valves which might contribute to the symptom.

Recently Zweig has reported seeing diverticula of the sigmoid. I had an opportunity to examine such a case, and could not see these structures for which I have been looking ever since I made my systematic study of disease of these structures in 1904. I doubt very much whether they can be seen in the oblique view obtained through a long tube, as they are none too easy to detect even in the fresh state when the bowel lies opened in the examiner's hand, unless he probes between the folds of the mucous membrane.

These few illustrative cases show clearly, without drawing further on my extensive list of interesting and useful observations, how valuable is direct inspection of the bowel, regardless of the therapeutic applications that can be made through these tubes. These lines were penned to call attention once more to the great value of direct inspection of the lower bowel as a diagnostic aid, and if I succeed in stimulating some others to do this work systematically I feel sure many patients will greatly profit.

INEBRIETY.*

ITS COMMON-SENSE CONSIDERATION WITH A VIEW OF ELICITING ITS CURE, PREVENTION, SUPPRESSION AND FINAL ERADICATION.

By DE LANCY CARTER, M.D.,

NEW YORK.

For the purposes of this paper, which is a plea for common-sense treatment of inebriety, we are of necessity limited to a consideration of a fully developed condition, it matters not how it may have developed or what may have been the underlying conditions. By this we mean whether there be a neurotic taint, a predisposition, an inherited tendency, or what not, this not a question, we have only under consideration the developed disease, that peculiar variety of insanity known as inebriety; therefore we accept all varying influences which have been at work to produce the disease, we know the family, social, and business relations which have been broken, and our only concern is the possession of the person, the victim of the disease, and the determination of what is to be done and how best to do it, knowing that our results depend altogether upon two possibilities.

Now, then, what is inebriety? We say at once that it is a form of insanity, in which persons have illusions, delusions, and hallucinations, which so modify their actions as to call attention to themselves of the world at large. Medical and legal authorities in particular look upon them as insane, their loss of self-control being considered to-day as an expression of a diseased process, as a symptom of an actual pathological change, is of such importance that a special thought is given to their consideration and much energy of time and money are expended to afford hospitals for their care, where proper treatment may be applied for their recovery and restoration to society. Or if such a happy solution may not be, asylums are established for them in accordance with new conditions necessitated by their mental change. These people are not placed in the criminal class, for while it is true that a process of law is invoked in order that they may be placed under proper restraint this action does not class them as criminals, and the consideration of their life's history with a view of eliciting the cause of their trouble does not place upon them the ban of the world, but rather rouses sympathy, for a most unfortunate condition. To-day inebriety is looked upon as a disease, and while there is no organ of the body exempt from alcoholic attack and consequent disorder, the nervous system is particularly affected and the mental processes are so altered that the individual is to all intent and purposes insane; without self-control and therefore equally deserving of the same control, restraint, treatment and consideration that is afforded the insane from causes other than alcoholic. The question of inebriety is universal in its applicability; age cannot wither nor custom stale its infinite variety; octopoid in its grasping reach and hydraheaded in its wonderful ability for reappearance and subtlety of resource in resistance, it seems almost as if efforts more than human were necessary for its solution. As a moral issue its treatment has only resulted in unsuccessful exploition; civic consideration has simply fixed a canker on the body politic; magisterial and police considerations of the question have only added to the already large amount of human misery, disgrace, and degradation.

What is left? A common-sense consideration of the whole matter as a disease, in its present proportions to be looked upon as an universally disseminated plague, a pestilence, and the measures to meet such a condition should be international, with each country, state, county, and district applying to its own quota of inebriates such rules and regulations as the nation, sitting together as a committee of the whole, may formulate. That it is a disease is universally accepted: that its major activity results in nervous and mental degeneration is a truism having as a natural corollary its proper consideration as a variety of insanity. Its true place for successful cure is in an institution, so arranged as to meet the almost infinite indications. Such an institution should be of necessity medical, and fully and completely controlled and conducted by medical men. You must pardon reiteration, but it cannot be too forcibly insisted upon, that to-day the fact exists that the inebriate is insane, being insane he is diseased; treat him then as a sick man. Human nature has always been controlled by opposing inclinations and desires, and if in the long run the desire for drink has overcome the aspirations for things decent and respectable, if self-control and self-restraint are practically lost, then place the individual in a position where control and restraint can be afforded together with the proper means for complete physical restoration; make of the hospital for the inebriate an asylum for the restoration of all his faculties, mental and physical alike, constantly bearing in mind that self-respect is a large element in the process at this time. We are especially interested in a condition, not a theory—the condition of inebriety. That drunkards are made every day, that it seems almost useless to try and stem the tide which appears beyond control, that the facilities for making of inebriates are legalized and protected by law is not now germane, the question only being the fact of inebriety, the existence of inebriates, and the forceful necessity for such consideration of this fact as shall restore to life, health, and happiness, to practical every-day usefulness, the greatest number possible of those unfortunates who are the dregs of society and burden of the body politic. Experience proves that inebriety is capable of cure, the question is the best way to go about producing this cure. Accepting the proposition that the inebriate is insane, a subject of illusions, delusions, and hallucinations without self-control, possessed of no respect either for himself or others in his present condition while at large, he is surely a menace to society. No one would think of trying for the successful treatment of other forms of insanity outside of properly adapted and conducted hospitals; then why is an exception made of this form of insanity?

*Read before the American Medical Society for the Study of Alcohol and Other Narcotics at their semi-annual meeting at Philadelphia, April 6 and 7, 1910.

We can all remember when an insane person was looked upon as a sort of wild animal, was kept in a straight-jacket in a poorhouse cellar, when in a word any person upon whom a suspicion of mental derangement fell was made a public charge, anathematized, and loathed. When the first sane idea of the necessity of considering insane people as diseased seemed to percolate through the consciousness of the public the poor unfortunates were herded in crowds together, and all treated or maltreated alike; classification in insanity has been a slow process and the splendid asylums of to-day have taken years for their development. The trouble has been that up to this time almost invariably the chronic drunkard has been looked upon as a criminal and needing only the care of the police. Now in our opinion this is a vital error, a great mistake, a potent reason for the meager success so far attending attempts at curing the inebriate. The fact should not be forgotten for a moment that we are dealing but with a mentally diseased person, and this introduces the second proposition, that the first step toward a cure is to take the unfortunate victim out of the criminal category and place him where he belongs; class him as sick, mentally diseased, insane. Get the possession of the inebriates, have them under control in the proper institutions, then if you like classify them to your heart's content. The corollary of this proposition is the necessity for the establishment of hospitals especially adapted to care for this form of insanity. At first this seeems almost a physical impossibility, the order is of necessity so large as almost to be incapable of being filled, but make an effort, establish institutions, place them in charge of the medical profession; good results must and will follow. Judge from analogy as to the ability of the profession to do things; see what sanitation has done, and who is back of it? The medical profession don't split hairs whether or not an alcohol maniac is or is not an inebriate. Prevention is better than cure; once on the road the alcoholic is sure to eventuate as an inebriate; then take him early and save him in time to do himself and the world some good. Government, general and local, must take the matter in hand. Let each community establish a commission to consider the matter in all its details, and if successful such good will be done as to make the world better and bring joy, peace, and happiness to those on earth who to-day are in squalor, sordid misery, abject poverty and wretchedness because of the chronic drunkard. The remedy is plain, but to obtain the means is a tremendous task; authority to act must first be obtained, and conditions are such that appeals to government, city or state, seems to fall upon deaf ears. So many are interested directly or indirectly in the liquor business that an appeal for money or even for authority to act, when private means are supplied, seems such an attack upon their business that all such efforts are foredoomed to defeat. However, by constantly insisting success will follow.

Now what is needed, and I cannot repeat it too often, is places where the unfortunate victims shall be treated for the disease which possesses them, institutions situated in reasonably accessible places so constructed, adapted, arranged, and conducted that every indication of each case shall be met. Commitment for such time as shall be needed to perfect a cure is necessary; a cure means re-establishment of self-respect in a physically healthy body controlled by a mind restored to a full appreciation of its possessor's duty to himself and the world. This is a large order, but it can be filled. The condition being a disease the institution is of necessity medical; medical men fully equipped by a knowledge of the subject obtained by large experience should have full charge of all departments. The fact that an institution is medical does not imply that the only means of cure is found in the drug department; far from it; everything which may or shall lend itself to the task presented, that of curing the inebriate of his alcoholic tendencies, is to be looked upon as a therapeutical measure. The institution should have within its borders general hospital appliances so that the necessary medical means shall be on hand to meet the indications of the case when admitted; as improvement takes place convalescent wards or departments with means adapted to assist in the advancement of the cure; as the patient gets in condition means to set him at work at physical labor shall be provided. To this end departments of various trades, in-door and out, plenty of room for gardening and farming, in fact anything and everything should be furnished for the accomplishment of the object. All this calls for a lot of money to be sure. Full and earnest consideration should be given the matter by qualified men, so that it seems advisable to appoint a commission with power to obtain all possible knowledge on the subject, and to formulate a plan comprehensive in scope so that those in authority to act in the matter, either the city government on one hand or the state on the other, shall have presented to them an intelligently worked-out plan simply and concisely stated.

No man with a grain of humanity in his make-up questions the necessity for immediate action in the premises, and it certainly seems impossible to think that any one should deliberately refuse to extend a helping hand at a time when it is so plainly needed. Therefore, in conclusion, it is respectfully suggested that the matter be brought to the attention of the legislators in session in each state, in such a manner as best meets the approval of this society now assembled, in order to have commissions appointed by the Governor of each state approved by each Legislature, whose duties shall be fully to consider the matter and formulate plans or arrange bills for presentation to said Legislature for their consideration. If smallpox and all infections or contagious diseases deserve the attention they are now receiving, no one may doubt the contagious and infective powers of alcoholic beverages, or question the propriety for similar action to repel their pernicious influences.

So, gentlemen, finally I have come before you at this session of our association to seek your aid in the furtherance of this object. So far the time has been largely expended in a consideration of the etiology, symptomatology, and pathology of the disease in question and we have now reached the time when there is forced upon us with horrible insistance the necessity for a formulation of a plan of practical treatment, and there cannot be too much pressure brought to bear to secure the success of such lines of treatment as I have outlined before you. The world at large must be brought to a realizing sense of its vital interests in this question, for beyond a doubt alcohol is at the root, if not the root itself, of all disease and of most of the misfortune which affect mankind in general. While you gentlemen are fully aware of the immensity of the question and realize its true relations

to the every-day life of every community, it is for you to impart that knowledge to the people; to force upon them the same realizing sense as you possess of the power of the evil you seek to suppress. Familiarity breeds contempt, and alongside of the care of the disease must go the prevention and this you know is altogether a matter of education and environment. Finally let me urge you to an unwearied and persistent, constant and unwavering forcing upon the universal attention the necessity for the accomplishment of our main object, which is the eradication of the use of alcohol as a beverage, keeping persistently at it until finally the idea percolates into the inner consciousness of the body politic and the goal is reached.

1030 Park Ave.

IS STERILIZATION OF THE HABITUAL CRIMINAL JUSTIFIABLE?

By CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE AT NEW YORK; VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS; PRESIDENT AMERICAN GUILD OF ST. LUKE; SURGEON OF POLICE, CITY OF NEW YORK.

In the year 1893 Dr. F. E. Daniel of Texas proposed total ablation of the penis, scotum, and testicles as a punishment for persons convicted of certain crimes. This operation was so radical as to excite horror in the average mind, and to provoke condemnation for its sweeping barbarity. The operation failed to find favor, but the idea imbedded in the proposal took root, and in 1898 the Superintendent of a Kansas institution for the feeble-minded performed castration upon 48 boys and reported favorable results. In the year 1899 Dr. H. C. Sharpe performed vasectomy upon, and by consent of, some of the inmates of a reformatory at Jeffersonville, Ind., and advocated his method with such persistency that in 1907 a statute was passed by that State legalizing Dr. Sharpe's method of procedure. This law is in force to-day. In 1905 a similar bill had passed the Pennsylvania Legislature, but had failed to receive the Governor's approval. Between 1899 and 1907 Dr. Sharpe had operated on 456 cases, and states, in the *Journal of the American Medical Association* for December 4, 1909, that he had never seen any unfavorable symptoms. Since that time the subject has received the careful consideration of those who have official charge of criminals and of the defective classes, and there is much discrepancy of opinion as to its justification. Those who would answer this question in the affirmative base their conclusions entirely upon the subject of heredity. They assume that a man with a criminal mind has a criminal brain, and that he will beget offspring with criminal minds and criminal brains. Yet no examination of the brain of any criminal has ever shown why he was a criminal, nor has any scholar's brain ever shown why he was a scholar. Even if the criminal brain showed definite characteristics, there is no evidence to show that such a brain would be transmissible to descendants by heredity. Embryology proves that whatever is inherited must be contained in the chromosomes formed by the fusion of the male and female element, and that the possibilities of inheritance are limited to the fact that a new and distinct life begins. Anything that happens afterward, affecting such life, is acquired, not inherited. Heredity only determines the species' characteristics, such as physical form, as evidenced by shape, size and color. Physical abnormalities, susceptibility to certain diseases, defects in physical development, are transmissible, but mental and moral abnormalities or defects are acquired traits, and entirely beyond the explanations of embryology.

Yet upon so entirely hypothetical and shaky a foundation as the theories of heredity, and not upon the established facts of embryology, have certain individuals, and some States, advocated surgical operation upon the male and female criminal in order to prevent procreation. Crime and criminality are attributes of the mind, and mind is not inherited. It is a postnatal acquirement, and a weak mind is rather the result of parental unfitness and improper environment than of any inherited structure. While it is unfortunately true that the present cost of crime and defectiveness is enormous, society cannot hope to recoup itself by any measure so pitifully inefficient, and so palpably absurd, as the mutilation of the criminal, or of the unfit. Ethically and morally the proposition is indefensible. Biologically it is foolish. The oft-quoted comparison between the unfortunate Jukes family and the talented Jonathan Edwards family, instead of proving the case of heredity, only serves to show what correct living and proper environments can accomplish in the one instance, as against segregation of unfortunates in surroundings of vice in the other. Of course a physically weak, or a sexually exhausted, parent cannot have other than a weak progeny, who will be easily susceptible to invasion by an infectious disease, but our experience with tuberculosis has demonstrated that environment rather than heredity must ever play the more important part, even in physical ailments. And crime, which is the voluntary act of a sane mentality, is an entirely postnatal acquirement, and dependent entirely upon environment. With the recent advances in biology, embryology, bacteriology, and physiological chemistry, showing us how much we can do to improve environment, the day is not far distant when that bugbear of antiquity—heredity—will cease to make the sociological outlook one of despair. And the physician of to-day will rise to be the teacher of to-morrow, to whom the multitude, forsaking false gods and false prophets, will confidently turn for enlightenment.

How, then, shall we improve the environment of those who are born into criminal surroundings, or early introduced into vicious company? Two factors conspire to make criminals of the young; lack of self-control and absence of fixed purpose of perseverance. The remedies for both are discipline and education. Our present system of public education is well designed to accomplish the greatest good to the greatest number, but it leaves much—perhaps too much—to the parents, and, until very recently, made little or no provision for the defective child, and completely ignored the possibility of his having a defective environment during the 7,760 hours in each year when he was not in school. But a better day is dawning for the incorrigible, the truant, and the vicious lad, or the wayward girl. Society is taking hold of their cases earlier in the hope of preventing environment from making a hopeless criminal instead of a useful citizen. The probation system, parole, the indeterminate sentence, and reformatories for first offenders, all help to reduce the habitual criminal class and would seem more potent than the passage of a law which makes legal punishment take on the aspect of revenge and

which is debasing alike to the victim and to the State. No law of the State has any right to exact revenge. Legal punishment has three functions: Medicinal, deterrent, and retributive. As punishment is medicinal, it serves the offender; as it is deterrent, it serves the commonwealth; and as it is retributive, it serves the offended party, being a reparation offered to him. To deprive the criminal of the power to procreate, while leaving him the power to indulge in promiscuous intercourse, would not fulfill any of these three functions, even if the procedure itself were legally, ethically, or morally justifiable. As a *specific* for crime *any* punishment is a failure. Yet punishment of some kind and degree is necessary for the prevention of crime in general, and for the management of the criminal in particular, and every evil deed must be met with that form of punishment "which will enter into the mind of, excite horror in, and disenchant the recipient." But it is not necessary that it should include a manifestation of that innate savagery from which the human race is not yet quite free, despite centuries of progressive civilization. The first duty of society is self-defense, not revenge. Its next duty is to restore, if possible, the criminal to the world as a healthy and useful unit, or, if he prove incurable and irredeemable, to seclude him permanently from society.

If the operation for sterilization is ever to command general approval, it must be voluntary on the part of the person undergoing it, and not compulsory. The idea of sterilization as punishment is not only barbarous, but degrading, and unlikely to have any beneficial effect, as it would return the victim to society with all his anti-social instincts aroused and thirsting only for vengeance.

42 East Twenty-ninth Street.

ASPHYXIA OF THE NEWBORN RELIEVED BY PLACENTAL AERATION.

By M. H. FREUND, M.D.,

NEW YORK.

In connection with a series of cases reported by Dr. W. E. Fitch in *Pediatrics,* October, 1910, in which infants born in a state of asphyxia were resuscitated by aeration of the maternal surface of the placenta, I wish to report the following case:

Mrs. M. B., 21 years of age, Russian, primipara, was admitted to the obstetrical service of the Sydenham Hospital on November 3, 1910, at 8:30 A. M. She had been in labor 24 hours at the time of admission, not having had any medical attendant previous to that time. Status on admission: Temperature, 98.8°; pulse, 90, of good quality; respiration, 24. External measurements: Interspinous diameter, 22 cm.; intercristal diameter, 25 cm.; external conjugate, 15½ cm. Fetal heart sounds between relaxations 110 to 114 per minute, going below 100 during uterine contraction. Length of patient, 145 cm.; small type woman; no deformities; fundus under the ribs; abdomen ovoid, protruding. In spite of two injections of morphine and scopolamine hydrobromate the uterus was almost in a state of tetany; pains occurred every minute with very slight relaxations during the intervals; uterus during contraction was exceptionally hard and tense; position of child ROA. The head was firm in the pelvic brim, having entered with a small segment only, brow palpable to the left. Two hours after admission the patient showed signs of exhaustion and rising temperature, in view of which and of the condition of the fetal heart sounds as previously mentioned, immediate delivery was decided upon. A third injection of morphine and scopolamine hydrobromate was given and the patient was then delivered by Dr. Jarmulowsky with the Tarnier-axistraction forceps. The mother was under chloroform anesthesia during a period of 15 minutes, receiving 15 grams of the anesthetic.

The child on birth was asphyxiated, skin livid, heart beating visibly, and pulsations in the cord distinctly palpable. There was no effort at normal respiration. The placenta was at once manually loosened and delivered. The child was placed in a basin of warm water, the placenta being held maternal surface upward, exposed to the air, and washed with warm water to free it of blood clots. After a few minutes the child, though making no attempts at respiration, improved in color, as did the pulsation in the cord in quality and quantity. Thus during thirty-five minutes respiration through the exposed maternal surface of the placenta continued uninterrupted; the pulsations of the cord during this period of time were good, but decreased in number and were of decidedly worse quality as soon as the maternal surface of placenta was placed on the table. Whenever the child showed signs of cyanosis the turning of a stream of oxygen on to the maternal surface of the placenta brought about immediate recovery of color, and the pulse improved in quality. Now the cord was tied and cut; the child cried lustily and has since behaved like normally born children. To-day mother and child are perfectly well.

APPENDECTOMY WITH COCAINE ANALGESIA.*

REPORT OF SEVEN CASES.

By CHARLES R. HANCOCK, M.D.,

NEW YORK,

LECTURER ON SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

In presenting these cases to-night my object is to state the facts that particularly interest me in regard to cocaine analgesia in appendectomy.

Case I.—T. P., female, aged 7. Diagnosis, acute appendicitis; temperature 102°, pulse 168, on admission to the Polyclinic Hospital. Patient's condition was such as to contraindicate general anesthesia. Operation August 26, 1907. Endermic and hypodermic infiltrations with a 1 to 500 solution of cocaine were made through a McBurney incision. No pain was experienced until the peritoneum was reached, but when this membrane was being incised the child made quite an outcry of pain. The rest of the operation was practically painless. The appendix was found to be acutely inflamed, and general peritonitis existed. The region from which the appendix had been removed was loosely packed with narrow gauze, and a wet dressing of saline applied. The patient recovered and was discharged at the end of three weeks.

Case II.—J. B., male, aged 46, bridge-builder. Admitted to the Polyclinic Hospital on January 19, 1909, with all the symptoms of chronic, relapsing appendicitis. Operation, January 20, 1909, through an incision three inches long, parallel with, and one-half inch from, the median line, beginning one inch below the umbilicus, and splitting the right rectus muscle. Endermic and hypodermic infiltrations of a

*Read before the Polyclinic Clinical Society November 7, 1910.

1 to 500 solution of cocaine were first used, and an incision was then made down to the sheath of the rectus muscle. Next the same solution was injected under the sheath and into the rectus muscle. No cocaine was used in the peritoneum, which in this location is entirely free from sensation. The appendix was found so adherent to the cecum that it had to be clipped loose with the scissors. The operation necessitated the lifting up of the cecum through the incision. The whole procedure was practically painless. The patient left the operating room whistling, and said he had often had as much pain from a shave. This patient weighed in the neighborhood of two hundred, and had about three inches of fat on his abdomen. The wound was closed without drainage, and the patient left the hospital cured at the end of two weeks.

Case III.—M. J., male, aged 28, farmer. Admitted to the Polyclinic Hospital, February 25, 1909, with chronic appendicitis. Physical examination revealed a marked valvular heart lesion—in fact, a surgeon had refused to operate on account of this condition. The patient walked with a cane and could scarcely straighten himself in the erect posture. Operation, on February 26, 1909, with cocaine analgesia. The cecum was firmly bound down by adhesions, all of which were broken up, and the former and a considerable quantity of large intestine were brought up through the incision. There was no pain. The patient was discharged from the hospital on the tenth day in good condition.

Case IV.—M. B., male, age 31, clerk in a cigar store. Admitted to the Polyclinic Hospital on April 20, 1909. Operation, April 21, 1909, with cocaine analgesia. This patient had lymphangiectasis, which was discovered at the time of the operation. He made an uneventful recovery, leaving the hospital at the end of a week.

Case V.—T. S. O., female, aged 19. Was seen for the first time September 12, 1910, with symptoms of acute appendicitis. Operation, on same date with 1 to 500 solution of cocaine solution. The appendix was found to be actually inflamed and contained a fecal concretion near its tip. The patient made a good recovery, and afterward told her physician she would never think of advising any one to take ether for so simple an operation.

Case VI.—J. K., male, aged 22, waiter in a hotel. Was operated upon at the Polyclinic Hospital, September 9, 1910, with the same weak solution of cocaine. The appendix was inflamed and contained a fecal concretion. The patient left the hospital cured in two weeks.

Case VII.—H. M. S., male, aged 27, was operated upon October 14, 1910, with cocaine. This was the most difficult appendectomy I have ever encountered. The great omentum was attached to the tip of the appendix, making it necessary to excise a portion of this membrane. The appendix was adherent to the external iliac artery for the distance of two inches. On account of the great amount of induration and inflammation a narrow gauze drain was left in the lower end of the wound for a few days. The patient made a good recovery.

Summary of Technique.—It is necessary to secure free evacuation of the alimentary canal by calomel twenty-four hours before operation, unless the case requires immediate operation. The incision is made three inches long, one inch below the umbilicus, parallel with and one-half inch from the median line. One of the advantages of this incision over the Deaver incision is that you are away from the inferior epigastric vessels, and there is no danger of rupturing them while separating the fibers of the rectus muscle. Endermic and subdermic infiltrations of a 1 to 500 solution of cocaine are performed, and then the incision is made down to the sheath of the rectus. The same solution is then injected under the sheath and into the rectus muscle along the line to be divided. No attempt is made to cocainize the peritoneum, and in no case is there the slightest expression of pain when this membrane is being incised, while in the McBurney region the peritoneum is highly sensitive. No more cocaine is used after the rectus muscle is separated. As the adhesions are being broken up, no pain is felt unless strong traction is made upon the mesentery. Moderate pulling on this membrane does not produce pain. In all appendectomies the stump is treated after the method advised by Professor Wyeth, the appendix being ligated about one-fourth of an inch from its junction with a No. 2 silk ligature. The meso-appendix is ligated with No. 2 catgut, and the funnel-shaped stump left after the organ is cut away with the scissors, is disinfected with carbolic acid, the excess of which is neutralized with a drop or two of alcohol. There is no further technique of the stump.

Prevention of Insanity.—Jones urges that greater interest should be taken in the prevention of insanity, by creating a greater sense of responsibility in respect to all matters pertaining to human parenthood and realizing that the hereditary transmission of disease is a crime against the best interests of the race and must be punished. Such a public opinion would confer material benefit not only upon the present generation, but also upon those who are yet to come.—*The Practitioner.*

Prolonged, Cachectic Form of Cerebrospinal Meningitis.—Robert Debré describes a prolonged, cachectic form of cerebrospinal meningitis in which, after the first febrile attack has improved, there is a period of lessened symptoms, followed by a fresh attack of fever and severe symptoms, which is again followed by a remission of symptoms. The child gets into a condition of cachexia, with stiffened neck, in which he lies half stupid when not touched, but complains bitterly of pain when touched, his eries being heartrending. The body is much emaciated, the limbs stiffened in flexion, and the neck stiff. There are paresis of all the limbs, incontinence of urine, and bedsores. Reflexes are diminished or absent. After a time this condition may improve gradually and the patient recover without paralysis, but often with deafness or blindness. Autopsy shows thickening of the membranes, dilatation of the ventricles, which are filled with pus, and softening of the cortex. In these cases puncture of the spinal cord does not have the usual effects, the serum not being able to reach the brain or the major portion of the cord on account of the false membranes which have formed around the cord, which do not allow the serum to flow upward.—*La Presse Médicale.*

Pulmonary Emphysema and the Operative Method of Freund.—A. Borgherini relates the operative history of an old case of emphysema in a woman of sixty years of age, in whom the thorax was practically fixed, dyspnea severe, and bronchial attacks periodic, especially in the spring. In June, 1908, the thorax was rigid, dilated, and conspicuously barrel-shaped. There was slowing of the circulation in the small and large vessels. Stiasni executed the Freund operation, resecting the cartilages of the second, third, fourth, and fifth ribs on the left side, which were altered, enlarged, rigid, arched at the extremity so as to form an angle, and contorted in their longitudinal axes. The operation was well tolerated; the intensity of dyspnea diminished at once; on the fifteenth day the patient left the hospital in good general condition, with circulation and respiration improved. She continued to improve, took up her usual peasant's work, and to-day, two years from the operation, is entirely cured. She has normal circulation, and respiration, and is in good general condition, and able to work. A radiograph showed the operative result. The spirometer, cytometer, and stethograph, taken at various times during the two years, showed a progressive improvement in the respiratory process.—*La Riforma Medica.*

CHEMOIMMUNOLOGICAL STUDIES ON LOCALIZED INFECTIONS.

IN studying the defenses of the body against infecting organisms the tendency in the past has been to devote attention almost exclusively to the specific antibodies of the blood serum and to the phagocytes. Only recently has it been suggested that certain definite chemical substances produced within the body take part in these defenses. Thus it has been shown that substances extracted or expressed from leucocytes are not only bactericidal but also often hemolytic. These substances differ from the antibodies in being thermostabile and alcohol-soluble. Still more recently it has been shown by Noguchi that the activity of these extracts depends upon their content in certain higher unsaturated fatty acids or their alkaline soaps, while Klotz has demonstrated the presence of these soaps in inflammatory foci. The autolysis of tissues within the body sets free unsaturated fatty acids derived from cleavage of lecithin-like complexes, large quantities of which, and of fatty acids, have been extracted from the seat of resolving lobar pneumonia. The autolysis of leucocytes in an inflammatory focus yields the fatty complexes and finally the fatty acids and soaps. The disintegration of leucocytes and tissues resulting from local bacterial infection may aid the body in overcoming the latter by means of the bacteriolytic chemical substances.

The above facts are pointed out by Flexner in an introduction to a paper by Richard V. Lamar on the "Action on the Pneumococcus and Its Experimental Infections of Combined Sodium Oleate and Antipneumococcus Serum," which is published in the *Journal of Experimental Medicine*, January 5, 1911. It is further noted by Flexner that the decrease in the number and virulence of the pneumococci in the resolving exudate is but slightly the result of phagocytosis, and that some other agent must be invoked to explain their removal. It is upon this agent that Lamar's investigations throw considerable light.

These investigations showed that highly dilute solutions of the alkaline oleates, which do not suffice to alter appreciably the morphology or reproductive power of the pneumococci, nevertheless, produce profound changes in their structure. Pneumococci treated with sodium oleate become more subject to autolysis, as is indicated by both the rapidity and the perfection of the process of self-digestion, and at the same time they become subject to lysis. The lysis of the soaped pneumococci tends to be incomplete with normal serum and to be perfect with an immune antipneumococcic serum. When normal serum is employed the surviving pneumococci subsequently multiply either in the test tube or in the animal body, in the latter case producing fatal infection. When, on the other hand, an immune serum is employed lysis is complete, no multiplication occurs, the test tube mixture is sterilized and the inoculated animal is protected from infection.

It has been noted by Noguchi and von Leibermann that hemolysis and bacteriolysis by the unsaturated fatty acid soaps are inhibited hy the protein of the serum. Lamar finds that this inhibition can be prevented by the addition of an appropriate quantity of boric acid so that suitable mixtures of serum, soap, and boric acid can continue to exert a deleterious and solvent action on the pneumococci and the effect is greater when immune serum is employed in the mixtures.

Infection can not only be prevented when the above mixture is added to the pneumococci before injection into the peritoneal cavity of small animals but the infection can likewise be prevented when a therapeutic injection of a mixture of the three substances is made to follow the inoculation of normal, highly virulent diplococci. The limits of the activity of the therapeutic mixture are determined in part by the amount of protein to be overcome, and in part by the peculiarities of the infection occurring in highly susceptible animal species. The virulence of the pneumococci is somewhat diminished by the soap treatment, but the treated organisms are not rendered more subject to phagocytosis.

The action of the soap is apparently exerted upon the lipoidal moiety of the bacterial cells, through which they are rendered more pervious to serum constituents and brought under their deleterious and dissolving influence. The changes in the pneumococci here described probably have a prototype in the resolving exudate of a pneumonic process, so that it may be considered that they occur in the animal body in the course of spontaneous infection and constitute one of the conditions of the conquest of the organism by the body's forces. A certain conformity exists between the manner of destruction of the pneumococci in a pneumonic exudate and that in the artificially prepared soap-serum mixtures. In order to imitate outside of the body the conditions of the removal of pneumococci within the body, it does not suffice merely to study the reactions to leucocytes and serum and to conclude from these reactions the means which the body employs for the disposal of the diplococci; but it is necessary to invoke still other factors, among which are the effects of chemical substances present in exudates, of which the soaps represent one class. The failure hitherto to unify the reactions in test tubes with those occurring in the body in connection with the pneumococcus may be due to the fact that account was not taken of this class of chemical bodies.

Lamar concludes that whether the principle here

presented can be made applicable to the treatment of local pneumococcus infections in human beings is a pressing question. Its application to the treatment of local infections, to the seats of which the serum, soap, and boric-acid mixtures can be directly applied, particularly after evacuation of an inflammatory exudate, seems to offer promise. There can be no doubt that the investigations of Lamar open up a virgin field in medical research, and, significant as are the results that he has already obtained, one may confidently anticipate still greater discoveries in the near future.

ENZOOTIC PLAGUE IN THE UNITED STATES.

In the endeavor to prevent the further spread of bubonic plague which is now more or less prevalent in so many countries, a study of the history of the disease is of service, for it throws some light on the occurrence and continued existence of this dread epidemic. Prof. R. T. Hewlett, writing in *Nature*, December 17, on Oriental and bubonic plague and quoting largely from Professor Simpson's treatise on the disease, comments on a feature which has characterized plague from the earliest times, namely, the alternation of periods of widespread prevalence with periods of quiescence and complete intermission. Thus, in the fourteenth century in the course of three years plague decimated the whole of Europe, with an estimated destruction of one-fourth of the population. In the 15th, 16th, and 17th centuries there were frequent outbreaks in Europe, Asia, and Africa, more or less limited in extent, culminating in England in the great plague of London, with 97,306 burials in one year, of which 68,596 were attributed to plague, whereas in the five years preceding and succeeding this terrible visitation the normal annual number of burials in London ranged from about 15,000 to 20,000. Plague then rapidly disappeared from Western Europe, so that by the end of the 17th century it was practically extinct, and save for isolated outbreaks occurred only in Turkey, the Levant, Egypt, and Asia Minor. It was practically unknown to the present generation until 1894, when it reappeared in epidemic form, this time in Hong-Kong.

In the olden days little or nothing was known concerning the means by which plague was transmitted and kept alive, for the rôle played by animals in the conveyance of disease to man has been recognized only in recent times. At first the rat was held to be the sole harborer and disseminator of plague, but now many small animals have been convicted and yet more are under grave suspicion. Passed Assistant Surgeon W. C. Rucker, U. S. Public Health and Marine Hospital Service, writes in the *Military Surgeon*, January, 1911, dealing with the investigations of himself and coadjutors in California in regard to the spread of plague by certain small wild animals, notably by ground squirrels. Plague first manifested itself on a large scale in the United States in 1900, when an outbreak occurred in the Chinese quarter of San Francisco, and it was not until 1904, after having killed 225 people, that it was eradicated. In 1907 plague reappeared among rats and men in San Francisco, and for many reasons, the chief of which was that ground squirrels for food purposes were being continually brought into San Francisco, it was thought that infected fleas might have been brought into the city by these means. In 1908 four squirrels were discovered to have plague. In the spring of 1909 the Public Health and Marine Hospital Service began the regular examination of the ground squirrels in Contra Costa County. It was eventually discovered that about one-seventh of the total area of California was infected. Further, plague has been found in the wood rat, which exists in large numbers in all those States west of a line drawn from the southwest corner of North Dakota to Pensacola, Florida, and is also found in the Appalachian chain of mountains which extends from the Hudson River as far south as Northern Alabama.

Perhaps the most alarming discovery made is that by Passed Assistant Surgeon G. W. McCoy that squirrel fleas will transmit plague to rats and that rat fleas will carry the disease to squirrels. The disease, too, exists in chronic form in ground squirrels. Thus, as Rucker says, "There exists an ideal condition for the perpetuation of the disease without the extermination of the host, and in those places where the life zones of the suburban rat and the country squirrel overlap a rat plague epizootic may be started, these rats in turn communicating the disease to the city rat, which comes into more intimate contact with man from the starting point of an epidemic."

Rucker rightly points out that the task which confronts those who are engaged in limiting and eradicating plague in the United States is an herculean one. To destroy rats alone is an almost impossible task, and when ground squirrels and other animals of a like nature have to be wiped out it would seem as if the obstacles in the way of accomplishing this object were insurmountable. The most hopeful aspect of the situation in California lies in the fact that the State and county officials, the ranchers' associations, and the individual landowners have shown a willingness to cooperate with the Public Health and Marine Hospital service in the endeavor to exterminate rats and squirrels. The ranchers are especially willing to assist in this good work for the reason that the ground squirrels do an immense amount of damage to the crops. Rucker suggests that it might be wise to subject the rodent population of the entire nation to a careful examination in order to discover exactly how far the infection may be spread. So far as rats are concerned, in addition to destruction of the animals on scientific lines, paying especial attention to the destruction of breeding places, the main efforts should be centralized on keeping rats out of houses. Plague now seems to be smouldering in this country and in Great Britain, and if active and persistent steps are not taken to destroy the hosts, or at least keep them well under control, the disease may at any time again break out in most destructive form.

UNNECESSARY NOISE AND THE SOCIETY FOR ITS SUPPRESSION.

In every big city of the world there are street and other noises, many of which it would be needless to say are unnecessary. Perhaps of all the large centers of population New York is the foremost, both for the variety of the sounds which afflict the ear in the daytime and for those which not infrequently render night horrible. But in the case of most large cities it is only a question of degree in the noises, they differ in volume and quality and are all more or less obnoxious. One of the most unpleasant features of the noises of American cities is that the inhabitants of those situated near the sea, lakes, or large rivers, in addition to the clamor of the streets must submit to the strident hootings of tugs and steamboats. Many persons, however, who are well become to a great extent immune or at least indifferent to the jangle of the city, and although no good can come of it, yet on the other hand no particular injury to health will accrue to the strong. With the nervous and weak the conditions are not the same and these often suffer acutely from the effects of noise and especially from that which occurs in the night. It is those who are lying sick in the hospitals, which are generally placed in crowded localities, who are most to be pitied in this connection. The need of rest and therefore necessarily of quietude for many suffering from certain complaints is too obvious to require insistence. While the internal control of a hospital rests with its authorities, of course, the outside noises are beyond the hospital's jurisdiction. Yet there have been instances in which the municipal authorities have stopped certain night noises in the neighborhood of hospitals. Such an instance occurred in Birmingham, England, a few years ago, when the city clock, near the hospital, which loudly chimed each quarter of the hour to the distraction and hurt of the patients was not permitted to sound its notes in the night hours.

It would be superfluous to state that there may be always heard in the streets many avoidable noises, and therefore it is well that in this country a vigorous crusade has been undertaken against them. The Society for the Suppression of Unnecessary Noise already during its brief existence (its fourth annual meeting will be held on Tuesday of next week) has done some remarkably effective work. The results of its efforts, guided by its energetic president, Mrs. Isaac L. Rice, have been several times referred to in these columns. The hideous night noises on the river have been materially lessened and the official recognition of "hospital streets," with the warning signs conspicuously displayed on the corners limiting the hospital areas, has materially reduced the volume of sound formerly disturbing the patients; more effective even than that, perhaps, has been the awakening of the young conscience by the lectures and conferences of Mrs. Rice with the school children, in which the suffering caused by noisy play and inconsiderate shouting near hospitals was forcibly brought to the attention of her audiences. Not only have the children learned to be considerate of others, they have also learned the blessing of quiet, and many of them are now asking that school streets be made quiet the same as hospital streets so that they may have the windows open without the noise interfering with their work. The Fourth of July racket was practically suppressed last year in this city, largely as a result of the society's efforts, and incidentally with the blessing of stillness was a reduction in the number of casualties and a positive saving of life, the accidents having fallen from 552 in 1909 to 185 in 1910.

The suppression of unnecessary noise is a matter in which members of the medical profession can but take a deep interest and they should employ all the means in their power to assist this humane society in its excellent work.

THE ROBIN CASE.

Another instance of the dense ignorance of laymen in regard to mental derangement and its relation to responsibility was afforded last week by a jury in the case of Joseph G. Robin, indicted for grand larceny. Thirteen psychiatrists, after mature deliberation and the expenditure of a great deal of time, formed the opinion that the defendant was in such a condition as not to be able properly to instruct his counsel by reason of delusions and hyperquantivalent ideas. In the face of this professional opinion a hastily drawn jury of the kind so common nowadays formed an adverse opinion, and, ignoring the testimony of the two alienists who had been selected by the Court, and the two who were acting for the District Attorney, promptly decided that the man was sane, whereupon the presiding judge congratulated them upon their "horse sense" and said he "felt like throwing up his hat" before them in congratulation. The yellow journals and some others thereupon abused and ridiculed the medical men, declaring that the majesty of the law had been vindicated.

Notwithstanding this verdict and the approval of the judge, from the professional and every other point of view it would seem as if the four officially appointed psychiatrists, Drs. Allan McLane Hamilton, S. E. Jelliffe, C. L. Dana, and Pearce Bailey, such men as Drs. W. A. White of the Government Asylum at Washington and George T. Tuttle of the McLean Hospital, and the seven others in the case were wise in recommending temporary detention at a criminal asylum until Robin recovered from his acute condition and could be tried.

In this connection, attention may be directed to the plan followed by the authorities of the enlightened State of Massachusetts and other New England States where laws exist enabling the courts to commit doubtful indicted cases for observation, and it is to be hoped that a bill for such provision may be passed in New York. The ridiculous behavior of the petit jury is an indication of the ignorance and unfairness of other tribunals of this kind, and while many in our own profession deplore the occasional appearance in court of disreputable experts, they are justly indignant because of the fact that the attitude of a certain portion of the public is seemingly to pillory all medical men who give testimony in court.

News of the Week.

Death Rate for 1910.—While the phenomenally low death rate recorded throughout the United States for the year 1909 will probably not hold for 1910, the provisional estimates of the Census Bureau make a splendid showing. The revised figures, based on the latest census returns, show that the death rate for 1909 throughout the registration area was 14.4 per thousand, the lowest in the history of the country. The returns thus far for 1910 indicate a rate of about 15.0 for the registration area. In the District of Columbia the total number of deaths during 1910 was 6,513, and the rate, 19.6 per thousand of population; in 1909 the total number of deaths was 6,216, and the rate, 19.0. Comparison of the provisional death rates per thousand of population for 1910 with those of 1909, in those States in which about 80 per cent. of the deaths for 1910 have already been returned, is as follows: California, 13.5 in 1910; and 13.4 in 1909. Connecticut, 15.6 in 1910; and 15.0 in 1909. Indiana, 13.4 in 1910; and 12.9 in 1909. Maine, 16.7 in 1910; and 15.6 in 1909. Massachusetts, 16.0 in 1910; and 15.4 in 1909. Michigan, 14.0 in 1910; and 13.1 in 1909. New Hampshire, 16.7 in 1910; and 16.9 in 1909. New Jersey, 15.5 in 1910; and 14.7 in 1909. New York, 16.2 in 1910; and 15.7 in 1909. Pennsylvania, 15.6 in 1910; and 14.7 in 1909. Wisconsin, 11.8 in 1910; and 11.8 in 1909.

American Medico-Political League.—Under this imposing title a number of Chicago physicians have recently incorporated in Illinois, among them being: J. E. Waggoner, F. Tice, Lewis H. Bremerman, O. Tydings, Ralph H. Wheeler, and G. Frank Lydston. The purpose of the league as set forth in the charter is in part as follows: "To procure the establishment of a national bureau of health, divorced from politics; the establishment of a uniform standard of medical requirements in the several States of the Union; encouragement and cooperation with all movements and legislation for food reform which shall be fair and impartial and founded on scientific premises; encouragement of political preferment of physicians as tending to secure just representation for the profession; encouragement of measures for the correction of hospital and dispensary abuses of charity."

Low Death Rate.—For the year 1910 New York City had the lowest death rate in its history. The total number of deaths is given by the Department of Health as 76,764, making a rate of 15.98 per thousand. All causes of death amenable to sanitary control were diminished in 1910, the number of deaths from tuberculosis being 1,840 less than last year. On the other hand, there was an increase of 230 in the deaths from cancer, of 93 from heart disease, and of 23 from appendicitis. Births to the number of 129,080 were reported during the year, a rate of 26.55 per thousand, and the largest number in the city's records. There were 46,417 marriages, an increase of 4,904 over 1909.

Montefiore Home.—During the past year 1,114 patients were treated at the Montefiore Home for Chronic Invalids, New York, and at the country sanatorium, all of them, except forty-six, without charge. At the end of the year 472 were under treatment. Plans for the erection of new buildings at 210th street and Jerome avenue are under way and the building will probably be ready two years from now.

Yellow Fever on Gunboat.—An outbreak of yellow fever has been reported on the United States Gunboat *Marietta*, which sailed from Puerto Cortez, Honduras, on February 1, bound for Key West. Five cases have occurred among the crew. The vessel will be held at the Marine Hospital Quarantine Station at Dry Tortugas for thorough disinfection, and the crew, after being kept under observation for a suitable period, will be sent north to have the benefits of a colder climate.

Medical Lectures.—The Educational Alliance, New York, announces a series of lectures on medical topics, at the Alliance Hall. The first will be given by Dr. William M. Polk, president of the Academy of Medicine, on Thursday, February 23, on the subject of "Medical Ethics and Their Application to Practice"; the second by a lecturer to be announced on March 30, on "Gynecological Operations by the General Practitioner," and the third by Dr. J. Brettauer, gynecologist to Mt. Sinai Hospital, on April 23, on "The Secret Division of Fees."

Naples and Cholera.—Following a rumor that the relaxation of official supervision might be expected to lead to a further outbreak of cholera in Naples, and throughout Italy generally, the Italian Consul in New York calls attention to the precautions still being taken by the Government and states that, except for a few residual cases in the Province of Lecce, the entire country is free from the disease.

Leprosy Control.—Secretary Ballinger of the Department of the Interior has asked Congress for an appropriation of $30,000 in order that he may deal adequately with the numerous cases of leprosy that have appeared recently in Alaska. As Alaska has no quarantine laws, nor any means of affording protection from communicable disease of any kind, and as there is continual danger from Eskimos, Aleuts, and Indians, who are ignorant of the first principles of hygiene, Governor Clark of Alaska urges that the Marine Hospital Service be authorized to take jurisdiction of the cases.

MacDonald Memorial.—Governor Dix of New York has been named as president of the association formed to raise funds for a memorial to Dr. Willis G. MacDonald of Albany, who died recently. Former State Controller Martin H. Glynn and Dr. Samuel B. Ward of Albany were named as vice-presidents. A meeting of the association was held in the capitol on February 3 and plans were discussed for raising $100,000 for a laboratory building for the Albany Medical College.

Infantile Paralysis.—Since last November, when infantile paralysis was officially classed by the New York City Department of Health as communicable and physicians were required to report it as such, sixteen cases have occurred in the city: seven in the Bronx, seven in Brooklyn, and two in Manhattan. Queens and Richmond have been free from the disease. A number of cases have occurred also in the northern part of the State and the Rochester Academy of Medicine has asked State Commissioner of Health Porter to undertake an investigation and has petitioned the State Legislature for funds to carry on the work. Such appropriations have already been made by the Legislatures of several other States. The resolution adopted by the Rochester Academy declares that infantile paralysis is prevalent in Canada, along the Niagara frontier, and that because of the constant intercourse between Canada and New York there is great danger of infection. It is suggested that an agreement as to

quarantine of the disease between Ontario and New York would be most desirable.

Murder Up to Date.—St. Petersburg, Russia, is watching with interest the trial of one of its citizens accused of having committed murder by the administration of diphtheria toxin to his victim. The accused, a physician, is said to have made a secret confession to the police, which he has first modified and then retracted, to the effect that he was employed by a relative of the dead man to remove him without exciting suspicion, and that cholera germs were the means first chosen. These proving unsuccessful he easily obtained the diphtheria toxin.

Tuberculosis Inquiry.—A resolution has been introduced into the New York State Legislature proposing the appointment of a commission to investigate conditions in the State as regards tuberculosis, and to devise remedial legislation. It is suggested that the commission consist of three Assemblymen, two Senators, the State Commissioner of Health, and one physician to be selected by the Governor. Another resolution proposed an amendment to the Constitution authorizing the Legislature to set aside an area of a thousand acres or less in the Adirondack State Park on which may be erected a State Hospital for the treatment of tuberculosis. The backers of the resolution point out that a proposal to erect a county hospital for the treatment of the disease nearly always meets with opposition from the people of the neighborhood, but that a State institution in a State Park would interfere with no one, and would, therefore, have no objections to overcome.

Medical Society Wins.—The Appellate Division of the Supreme Court of New York has recently handed down a decision reversing the action of a lower court in awarding damages to Paul Schmidt in a suit brought against the New York County Medical Society for malicious prosecution. The Appellate Division holds unanimously that the County Society was justified in bringing Schmidt to trial on the charge of illegally practising medicine, although he was acquitted in the Court of Special Sessions. A new trial of the damage suit was ordered.

Plague in China.—The official reports from Pekin state that the plague there is well under control and that no new cases are appearing. There is a suspicion, however, that the real state of affairs is being concealed. No denial is made of the assertion that conditions throughout the Province of Harbin are very bad, and that thousands of deaths have occurred. A significant feature is the fact that the trip planned through the East for the Crown Prince of Germany has been abandoned.

Los Angeles a Mecca.—Four large medical conventions will be held in Los Angeles, Cal., next June. The American Medical Association, the American Association of Medical Editors, the American Academy of Medicine, and the Arizona Medical Association will meet simultaneously during the last week of the month.

Tuberculosis Dispensary.—The second free dispensary in the State of Illinois for the treatment of tuberculosis was opened in Springfield on January 23 by the Springfield Society for the Prevention of Tuberculosis.

Lectures at Cancer Hospital.—The governors of the New York Skin and Cancer Hospital announce the following course of lectures to be given in the Out-Patient Hall of the hospital, Second avenue and 19th street, New York, on Wednesday afternoons at 4.15 o'clock: March 1 and 8, Eczema, Dr. Bulkley; March 15 and 22, Acne, Dr. Bulkley; March 29, Psoriasis, Dr. Bulkley; April 5 and 12, Syphilis, Dr. Bulkley; April 19 and 26, Cancer, Dr. Bainbridge. The lectures will be abundantly illustrated by means of cases, models, colored plates, etc., and will aim at presenting the subjects in a practical and instructive manner. The course will be free to members of the medical profession on the presentation of their cards.

Dr. Charles H. May has been appointed consulting ophthalmologist on the Fourth Division of Bellevue Hospital, New York.

Beth Israel Hospital.—At the annual meeting of the Beth Israel Hospital on January 29 plans for erecting a new hospital building were discussed, the present building being much too small for the accommodation of all the patients desiring treatment. Of the total number of applicants during the past year, 1,317 were refused because of lack of room. In the hospital 2,114 patients received treatment, and in the dispensary 43,228, the total number of visits in the latter being 102,635. The accident ward received 1,827 cases. There were 232 deaths in the hospital during the year, making a death rate of 10.9 per hundred, which would be reduced to 8.1 per hundred if the number of those dying within forty-eight hours after admission were deducted.

Free Patients in New York.—The New York State Board of Charities estimates that during the year ending September 30, 1910, 39,883 persons received free treatment in the hospitals of the State which receive public money. During the same period 1,154,686 persons were treated in public and private dispensaries in the State, of whom only 33,189 resided outside of New York City.

Milk Inspection.—The Department of Health of New York City announces that it has decided to abolish within a few months the present grading of milk sold in the city, and to create instead the three grades A, B, and C. Grade A milk will be intended especially for the feeding of infants, and will be certified, guaranteed, or pasteurized according to special regulations of the department. Grade B milk for ordinary drinking purposes will be that of known origin, though not of the highest percentage of fat, and milk pasteurized according to the ordinary regulations of the department. Grade A milk will be sold only in bottles; Grade B milk will be sold either in bottles or in containers, but will not be dipped. No milk inferior to these grades is to be sold for drinking purposes. Grade C milk is to be known as "cooking milk," and will comprise all other milk complying with the departmental regulations. It will be sold from cans or in bottles.

Hospital Burned.—The Mercy Hospital of Altoona, Pa., was almost completely destroyed by a fire which broke out at two o'clock on the morning of February 1. All of the patients were removed without harm.

Gift for Dormitory.—The Hospital Association of Amsterdam, N. Y., has received a gift of $15,000 from Mr. William Sloane of New York, to be used for the erection of a nurses' dormitory. The gift is made as a memorial to Dr. Berry, Mr. Sloane's grandfather, who began his practice in Amsterdam in 1818.

Alumni Association of the Lying-In Hospital of the City of New York.—A stated meeting of this society will take place at the Harvard Club, 27 West Forty-fourth street, on Tuesday evening, February 14, 1911, at 8:15 o'clock. The paper of the evening will be read by John O. Polak, M.D., of

Brooklyn, and is entitled, "What we can expect from the vaccine treatment in puerperal sepsis."

The "Associated Physicians of Long Island" celebrated the thirty-ninth anniversary of its foundation by a dinner at the Hamilton Club on the evening of January 28. The toastmaster was Dr. Thomas R. French, and the speakers were Dr. D. Bryson Delavan, Surgeon-General Stokes of the Navy, and Naval Constructor William J. Baxter. The annual election of officers resulted in the selection of Dr. Frank Overton of Patchogue as *President;* Dr. James S. Cooley as *First Vice-president;* Dr. William B. Brinsmade as *Second Vice-president;* Dr. William A. Baker as *Third Vice-president;* Dr. James Cole Hancock as *Secretary,* and Dr. Charles B. Bacon as *Treasurer.* Surgeon-General Stokes and Dr. Delavan were elected honorary members.

The Late Dr. Lesem.—At a regular meeting of the Eastern Medical Society held on Friday, January 13, the attention of the society was called to the sudden and untimely death of one of its members, Dr. William W. Lesem. The society desires to express its deep sense of loss of a man highly esteemed, and wishes to convey to his family, as a token of respect and in reverence to his memory, its sincerest sympathies. (Signed) Harry E. Isaacs, Benjamin Rosenbluth, Jacob L. Maybaum, *Committee.*

Obituary Notes.—Dr. Hugh Campbell Hendry of Newark, N. J., a graduate of the Bellevue Hospital Medical College in 1872, at one time surgeon of the Newark Police Department, and a member of the Board of Education, died at his home of heart disease on January 28, aged 61 years.

Dr. Charles Edwin Wood of Brooklyn, N. Y., a graduate of the University of Michigan, Department of Medicine and Surgery in 1907, formerly attached to the United States Marine Hospital Service, died in the Brooklyn Hospital after a short illness on February 2, aged 29 years.

Dr. John W. Bond of Toledo, Ohio, a graduate of the New York University Medical College in 1846, a veteran of the Civil War, and for twenty-five years chief of staff of St. Vincent's Hospital, Toledo, died at his home on January 23, aged 86 years.

Dr. W. Monroe Smith of Atlanta, Ga., a graduate of the Atlanta Medical College in 1895, and of the New York Post-Graduate Medical School and Hospital in 1898, physician to the King's Daughters Hospital, and surgeon to the Tabernacle Infirmary and McVicar Hospital, Atlanta, a member of the American Medical Association, the Southwestern Medical Association, and the Georgia State and Fulton County Medical Societies, died suddenly on January 26, aged 38 years.

Dr. Tullio A. Rottanzi of San Francisco, Cal., a graduate of the Cooper Medical College of San Francisco in 1887, died at the German Hospital in that city of pneumonia on January 20, aged 43 years.

Dr. A. M. Jamerson of Hapeville, Ga., a graduate of the Southern Medical College of Atlanta in 1884, died suddenly at his home on January 25, aged 52 years.

Dr. Bernard W. Moore of St. Louis, Mo., a graduate of the University of Virginia, Department of Medicine, in 1894, and a member of the American Medical Association, died at his home of pneumonia after a short illness on January 22, aged 39 years.

Correspondence.

A DEATH FROM GAS AND OXYGEN ANESTHESIA.

To the Editor of the Medical Record:

Sir:—In the Medical Record, November 12, 1910, I reported a case under the above title. I have since discovered that the report was inaccurate, and therefore misleading. For special reasons I had arranged with the anesthetist for the administration of gas and oxygen. It seems that, as the gas and oxygen did not act in a manner satisfactory to the anesthetist, he added a small quantity of ether, without mentioning the fact to me. In subsequently discussing the case, he unfortunately did not inform me of the change that had been made in the anesthesia. Quite naturally, I did not inquire whether any change had been made. Soon after the case was published, I received a number of inquiries as to the technique employed, and the apparatus used in the anesthesia. I referred the writers to the gentleman who administered the anesthetic, and was then informed by him that a very small quantity of ether was used, the death occurring almost immediately after the ether was added to the gas and oxygen. I doubt if the addition of the ether was responsible for the untoward result of the anesthesia, but it is only fair to make the foregoing correction of the report, and, in any event, the addition of ether to the anesthetic makes it unjust to classify the case as "a death from gas and oxygen anesthesia."

G. Frank Lydston, M.D.

Chicago.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SLEEPING-SICKNESS CONFERENCE—PUBLIC HEALTH IN RELATION TO INDUSTRIAL DISEASES—MEETINGS OF ROYAL COMMISSION ON MINES AND QUARRIES AND ASSOCIATION OF M. O. H.—OCULAR AND VISIONAL CONDITIONS IN MEDICAL CASES—ACTION AGAINST A SURGEON—OBITUARY.

London, January 20, 1911.

An informal conference is sitting at the Foreign Office on sleeping sickness, with special reference to the risk of its spreading in consequence of the linking up the railways running or projected between Rhodesia and the Congo frontier. The Belgian government is represented as well as the railway companies, the British and foreign colonial offices, the sleeping-sickness bureau and the chartered company. The conference was opened by Sir A. Nicolson, who welcomed the delegates in behalf of the government, and spoke of the efforts made to cope with the disease. D. Van Campenhout of the Brussels colonial office replied on behalf of the delegates. The conference will discuss in detail all suggestions as to methods, local or other, for further study of the disease and the prevention of its spread, particularly in view of the extension of railways in Africa.

Recent events have given a pathetic interest to some of the problems of public health which have been brought before different assemblies. The Royal Commission on Metalliferous Mines and Quarries has been considering the subject of dust as to its effects on workmen.

Dr. Matthew Hay, professor at the University of Aberdeen and medical health officer for that city, gave important and practical information on the granite

quarrying and cutting, which is the leading industry of northeastern Scotland. There were three quarries within the city. Deep holes, sometimes twenty feet deep, were drilled into the granite, charged and exploded by gunpowder. Thus dislodged, it was split into blocks by drilling shallow holes and driving into them iron wedges. Deep drilling only gave a little dust at first, but shallow caused a good deal, and some must be inhaled by the workmen. Dust was also produced by crushing stones for road metal and concrete. This was done by machinery, to attend to which not many men were needed. Apart from dust the conditions were healthy, the work being done in the open air and good shelters provided. Danger arose when done in confined places and with machine tools; done by hand in open air it did not seem dangerous. To diminish phthisis among stone cutters persons from tuberculous families or whose chest development was unsatisfactory should not be apprenticed to the industry, and apparatus for diminishing the risk of inhalation of dust were desirable inventions.

Dr. E. L. Collins, medical inspector of factories for the Home Office, told the commission that he had been studying the effects of different forms of dust. Cotton dust, which was very light, led to a typical form of asthma. Coarse emery and glass dust caused the symptoms of old-age bronchitis—not phthisis. He found dust hindered normal chest expansion, and those exposed to it attained their maximum height at a later age. A difference in weight was more obvious in later years than that in height. Dust became dangerous in inverse ratio to its size, the fine being carried into the lungs more easily than the coarse. To cause fibrosis dust had to have a chemical constitution which the tissues could not break up and was therefore a foreign body when it reached those tissues. Silicious dust was particularly dangerous.

Mr. Robert McLaren, H. M. inspector of mines for western Scotland, stated that in his district the mines were chiefly limestone, and he had never seen a consumptive workman in them. But it was seen among those who worked up the stone in factories. If rock drilling were done in the open air the dust was at once dispersed and with it the danger.

Another meeting concerned with industrial diseases was that of the medical officers of health, who were addressed by Mr. Dearden, medical health officer for the Port of Manchester and president of the Association of Certifying Factory Surgeons. He spoke highly of the inspectorial staff, but condemned the department for ignoring the certifying surgeon without whose help the administration could not be perfect, although it had advanced beyond that of other nations. The incidence and fatality of industrial diseases and the sanitary supervision of workshops demanded the continual study of every medical health officer. Among the outside factors was alcoholism, and this seemed to pick out particular trades. The reason of this was often obvious, *e. g.* certain occupations excited excessive thirst. In glass works and rubber works the heat was excessive, and whenever work was done in confined spaces there was in addition the lassitude produced by imperfect ventilation and overcrowding. Waterproof cloth spreaders were subjected to naphtha fumes and were rapidly injured by alcohol, indulgence in which by workers in lead was suicidal. The rapid breakdown through alcoholism of men engaged in arduous occupations was illustrated in the iron and ship-building trades. Modern speeding up of machinery was a strain on energy tending to early collapse, well illustrated in the textile trades, metal stamping and power sewing machines. Working in compressed air could only be done during short periods, and in other dangerous processes short shifts were essential.

Mr. Dearden said that compulsory notification had done so much to abolish phosphorus poisoning that he was inclined to suggest that every worker in certain dangerous industries who became ill should be reported and the case investigated to determine whether the illness was attributable to his occupation.

Ocular and visual conditions in medical cases were discussed at the last meeting of the Medical Society of London. In a paper on this subject Dr. James Taylor made five classes of such conditions: (1) Of the pupil, (2) of ophthalmoplegia externa, (3) of optic nerve, (4) retinal changes, (5) hemianopia. As to (1) he said inequality was not necessarily grave. Argyll-Robertson pupil might occur in lesions near the third ventricle or be associated with tabes, paresis, or paraplegic or hemiplegic symptoms, wasting of the shoulder girdle, these being the results of syphilitic disease of vessels or cervical pachymeningitis. It might, however, appear as an isolated phenomenon. As to (2) sixth nerve paralysis was mentioned, and the question whether it ever resulted from neuritis due to cold. He had never seen it associated with seventh nerve affection. Optic atrophy was then discussed. It occurred in lesions at the chiasma, in which neuritis was rare. Optic neuritis was a common result of intracranial tumor. It was our early sign, in spite of contrary assertions.

The impairment of vision it caused was very often the first thing to attract the patient's notice. It was seen in toxic anemia. Retinal thrombosis was not always serious. Embolism of the central artery of the retina might occur after diphtheria without any recognizable sign of cardiac disease. Bitemporal hemianopia was always the result of a lesion at the chiasma.

Mr. Percy Flemming read another paper on the subject. He thought the connection of astigmatism with headaches might be too hastily assumed. Both were common and it was easier to have the eyes examined than to review every possible cause of headache. A little-known characteristic of hypermetropic headache was that it occurred on waking, and people thought it could not be due to the eyes after a good night's rest. His explanation was that the ciliary muscle was relaxed in sleep and waking was an act of looking at a near object. Unless the headache was clearly due to the ocular condition he would hesitate to correct half or a quarter diopter of hypermetropia or astigmatism. If the headache depended on the ocular condition no error of refraction was too unimportant to correct. A crucial test was that atropine removed an ocular headache but in some cases we could not apply atropine.

In the discussion that followed Mr. Higgins said double vision should have more attention from general practitioners. In two cases in men over sixty one died from tumor and the other from softening of the brain. Mr. Jessop said improvement under mercury was no proof of syphilis. Dr. Buzzard related a case of optic neuritis apparently due to alcohol and tobacco, and without central scotoma. Dr. Wilfred Harris said central scotoma might be the earliest symptom of pituitary tumor. Dr. Hawthorne said retrobulbar neuritis was sometimes the

first indication of disseminated sclerosis. Dr. French referred to cases recorded in Queensland of lead poisoning in children causing optic neuritis and paralysis of the sixth nerve. Other speakers said that unless atropine was used headaches from ocular conditions would be overlooked and that those who sent patients to oculists for report should insist on full examination being made.

Mr. Ryall, a well-known, skillful surgeon on the staff of the Cancer and Gordon Hospitals, has been subjected to a charge of negligence in an operation for abdominal tumor, but the action has ended in a complete vindication on every point submitted to the jury. It seems that unusual difficulties were encountered from adhesions, and a tear of the intestine occurred. The operator used a swab and sewed the rent over it as the best way to meet the emergency. In a few days the nurse reported the passage of the swab, but she seems to have mistaken a hard concretion for this, and the swab remained for months. Sir A. Fripp and Mr. E. Lane commended Mr. Ryall's resourcefulness in using the swab, and congratulated the patient on being alive. It was acknowledged that this use of a swab was a new departure. One surgeon, the only one called for the prosecution, said he had never used one, but he admitted the question of leaving it in was for the operator at the moment to decide.

Henry Power, consulting ophthalmic surgeon of St. Bartholomew's and the Royal Westminster Ophthalmic Hospital, died on the 18th inst. After a distinguished student career he qualified in 1857, took M.B., London, and F.R.C.S., 1854, and devoted himself to physiology and ophthalmology, becoming in due time president of the Ophthalmological Society, professor of surgery, Arris and Gale lecturer, and V. P. of the R. C. S. He edited the sixth to ninth editions of Carpenter's Physiology, 1864-76, translated Strieker's manual and Erb's nervous system in Ziemssen's Cyclopedia. He wrote his well-known "Manual of Physiology" and his "Illustrations of Diseases of the Eye," 1869. During his long career he filled many other offices and maintained in all the honor of the profession by which he was held in the highest esteem.

Dr. Wm. Taylor Morgan, J. P., died on the 11th inst, aged 79. He was M.D., Edin., 1858; M.R.C.S., 1859, and many years a magistrate for the County of Carnaroon.

Dr. John Edward Morris, who was for thirty-nine years medical health officer in Essex, has also died at the age of 65 He took M.R.C.S. in 1870 and M.D., Durham, 1885.

Dr. Walter Ridley, surgeon and laryngologist to the Royal Infirmary at Newcastle-on-Tyne, died on the 13th, aged 50. He was M.B.M.S., Durham, with honors, and F.R.C.S., Engl., 1890.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

RHINOPHARYNGITIS MUTILANS—CERTIFICATION OF MEAT—ANTITUBERCULOSIS SOCIETY—LEPROSY A HOUSE DISEASE—DAMAGE TO THE CULION LEPER COLONY—PLAGUE DANGER—SANTO TOMAS MEDICAL SCHOOL.

MANILA, December 1, 1910.

THE attitude which the Bureau of Health has maintained toward the disease gangosa seems to have been thoroughly vindicated. It may be remembered that gangosa (rhinopharyngitis mutilans) was not considered as a specific disease entity. It frequently happened that cases that were reported to the Bureau as gangosa were cured in a short time by the administration of iodide of potassium and mercury in ascending doses. The recent paper of Garrison, in which he reports that the many cases which had been isolated and cared for at Guam at public expense for so many years have all now been cured with similar treatment, adds strong confirmation to the Philippine experience. Cases of this disease are now even seldom reported.

The meat inspection law of the United States is not in effect in the Philippine Islands because Congress provided no machinery for its enforcement and the Philippine Legislature has not reenacted it here as was done with the Food and Drugs Act. On this account the admission of meat and meat products to the Philippine Islands has not been governed by the same procedure as obtains in the United States. The result of this has been that the American exporters have labored under a disadvantage in competing in the Philippine market because they came into competition with foreign importers who were not obliged to undergo the expense which is caused in the United States by the ante-mortem inspection which is required of meat and meat products. This has had the additional effect of flooding the Philippine market with meat products, the origin of which was at best obscure. But strange as it may seem, upon analysis of such products upon their arrival in the Philippines they were found as a rule to be superior, chemically speaking, to those produced in the United States. However, as the methods of packing such products in China became more and more known, it was deemed highly desirable that inspection of them should be made before they are admitted to the Philippine market. The authority contained in the Food and Drugs Act to exact a certificate along the lines given in Food Inspection 76 was invoked as far as fresh meats are concerned some months ago. The certificate of a responsible veterinarian was required which stated that the animals from which the meat was obtained had been slaughtered in a sanitary manner and that they were healthy. The Insular Government has now decided to extend this policy and similar certificates will be required for lard, ham, sausage, and all other meat products after February 1, 1911.

The Philippine Islands Anti-Tuberculosis Society has recently organized branches at Cebu and Zamboanga. Many of the prominent people of each city were elected officers of the society and its work was begun under favorable auspices. It is also proposed shortly to organize a similar society at Iloilo and other towns throughout the islands.

According to the Bureau of Health there is considerable evidence constantly coming to light which indicates that leprosy is a "house disease." For some years past it has been the policy of the Bureau to examine at semiannual intervals all persons who live in houses from which lepers had been removed. This has resulted in at least six cases of leprosy being found during the past month who are microscopically positive but in whom no clinical manifestations of the disease could be detected.

The destructive typhoon of the early part of November which passed through the Visayan Islands and caused losses to the amount of at least several million dollars also passed through the Culion Leper Colony and caused great destruction. It is estimated that the damages amount to at least

$15,000. The houses which were constructed of light materials were all seriously damaged. Twenty of them were completely destroyed and eighty others were seriously damaged and will require rebuilding. The causeway, wharf, and embankment for the tramway were almost completely destroyed. After the passage of the storm at least 1,000 lepers had no roofs over their heads. It is remarkable that a storm which was so destructive should have caused so few fatalities. At Culion no one was killed and only two persons were slightly injured. The damages at Culion will cause some delay in the collection of lepers and will probably retard the date of the extinction of this disease.

The Moro Province has been maintaining an entirely distinct health service, appointing its own officers and employees and providing for their salaries from its own revenues. As its resources were very meager, however, the Insular Government has come to the rescue and has agreed to provide for the lepers of the Moro Province at Culion. In accordance with this policy the lepers from Zamboanga and vicinity were transferred to Culion on November 22.

The Eastern Chinese coast, particularly the ports in Indo China, are becoming more and more infected with plague, and on account of the increasing frequency with which ships arrive in the Philippines from such ports the United States Quarantine authorities have imposed stricter antiplague measures. Vessels from such ports must regularly be fumigated for the destruction of rats and vermin and must be kept at least six feet away from wharves in the Philippines and proper rat guards used. The crews and steerage passengers will not be allowed to land in the Philippines until at least seven days have elapsed from the date of the last probable exposure to plague.

The officials of the Santo Tomas Medical School and also of the Santo Tomas Pharmaceutical School have been able to make temporary arrangements with the Papal authorities in Rome for the continuance of these two institutions at least through the present term. It will be remembered that by recent decision of the Pope the buildings in which the medical school was located were transferred from the Dominican Order to Jesuits and that the latter Order decided not to continue these schools. Immediately afterward riots took place among the medical and pharmaceutical students which were kept up until a more favorable decision was received from Rome.

Herbert Leslie Burrell.—E. H. Bradford, F. S. Watson, and G. H. Monks present their tributes to the memory of the late eminent Boston surgeon.

Time and Method for Prostatectomy.—B. Tenney states that there are three classes of men over forty who consult a physician for symptoms which may be due to prostatic obstruction. First, those with residual urine, without cystitis, whose complaint is of frequent urination, night urination, difficult urination, or albuminuria. Second, those with residual urine and infected bladders. Third, those more or less dependent on a catheter. Should one operate on these early cases? If we can relieve the obstruction by massage, sounds, dilators, the answer is, No. So long as a man can empty his bladder there is no good reason for removing an organ which may trouble him later but does not now. The second class of patients includes the majority of all who call for help. They have not begun to use a catheter and they are often ignorant of the condition which sends them to a physician. They are slowly going down hill, losing sleep, losing strength, growing old faster than their years warrant. Their urines are alkaline, contain a little albumen, often a few casts of white and red blood corpuscles. They rise two or more times at night to urinate and pass urine every two or three hours by day. Many of them think they have a "little kidney trouble" and have gone the rounds of physicians and proprietary remedies. For these patients there are but two alternatives; one can put them into the third class and let them use a catheter more or less frequently, or one can operate. There is no other alternative if they are to live with any comfort. The first alternative is often chosen from fear of death from the operation and sometimes from the knowledge of some one who has been operated upon and has incontinence or the need of using a catheter after the operation. The third group will include all who use a catheter one or more times daily. If they are entirely comfortable using a catheter four or six times in twenty-four hours they may safely be allowed to continue if they prefer it, but they should have the option of the operation and freedom from such annoyance. Such cases are ideal for operation because of their proved resistance to infection, their toleration of urethral instruments, their normal bladder capacity, and the probability of a definite, easily removed obstruction. The author believes in the operation of suprapubic cystotomy because one is dealing with a tumor which is partially intravesical at least; because even the largest prostates can be removed entire or in two pieces without injury to rectum, sphincter, or ejaculatory ducts; because recent studies of hypertrophied prostates show cancer formation to be comparatively frequent and morcellation, therefore, undesirable; because the slight excess of mortality does not seem necessary if enucleation be downward and the after-care correct; because it has given results satisfactory to patients.

Medical Problems of Alcoholism.—I. H. Neff discusses a number of these problems. Thus it is instanced that the relation of poverty to drunkenness, or the dependence of alcoholism on heredity, has never been accurately determined. It is quite necessary to make a sharp distinction between the effects of alcohol itself and the effects of certain other factors which also are usually present in the life of the alcoholic.

Foreign Body in Trachea and Status Lymphaticus.—J. P. Clark and O. Richardson report the case of a sixteen-month-old infant, who following an operation for removal of a peanut kernel from the trachea, which operation was done under light ether anesthesia, died suddenly. Autopsy disclosed the status lymphaticus, with greatly enlarged thymus. There was no evidence that this caused mechanical compression of the trachea. Death was apparently due to hyperthymization, a toxemia affecting the nerve centers.

Bronchoscopy for Foreign Bodies.—D. C. Greene in reporting three cases emphasizes the following three points which seem to be demonstrated in reviewing these cases: (1) In bronchoscopy for recovering a foreign body which plugs a bronchus, it is important to use a tube which is provided with many fenestra at its lower part. (2) In bronchoscopy for recovering a long, pointed object, such as a pin or a needle, the necessity for fenestra is

not so great, and their presence may cause a dangerous complication to the operation. (3) Bronchoscopy may be performed even in the presence of an acute inflammatory process in the lung without necessarily causing any ill effects.

Hemorrhage After Tonsillectomy.—H. A. Barnes describes the following methods to be resorted to in the management of hemorrhage following tonsillectomy. These are given in the order of their simplicity: First, simple pressure. Second, ligation of the bleeding point or points. Third, suturing of the faucial pillars.

Abuse of Urethral Instrumentation. G. Greenberg.

The Eyes and Chronic Spasms of the Neck and Face.—G. T. Stevens has from time to time called attention to the important relation which exists between the habitual pose of the body, as well as the muscular expression of the face, and the peculiarities in the adjustment of the eyes within the orbits. The author devotes attention to two forms of chronic spasm, namely, torticollis and tonic and chronic spasm of the facial muscles. He states that the position of the head in torticollis is a fixed exaggeration of the habitual carriage of the person subject to the affection before the spasm occurred. Granting this, it is not difficult to see that as a result of habitual and perhaps fatiguing contractions of certain groups of muscles, especially under certain conditions, the habitual carriage of the head might well induce the spasm of the group of muscles habitually overworked.

Carcinoma of Ileum.—A. Bassler and J. P. Grant present the report of a recent case under their observation which is of interest for the following reasons: 1. An attack of typhoid fever (the ulceration in which is mostly in the ileum) may have had to do with the development of carcinoma at some local site of cicatrix formation of the healed typhoid ulcer; 2, there had been no vomiting in the course of the cancer growth, same being of possibly eighteen months' duration, this being particularly of interest when the degree of peristalsis present in the case so strongly suggested a marked stenosis in the small intestine, and the fact that the first vomiting spell was fecal in type; 3, the marked degree of visible peristalsis which could be traced from the ileum up and which required the additional force of the stomach to drive the contents in the small intestine through the strictured ileum; the good condition of the general body, considering that the cancer was far advanced; and, 4, the operation of lateral anastomosis of the middle ileum (which is very movable) with the ascending colon (which is fixed) in such a way as to have an anchored receiving part of the union to which a very movable viscus (ileum) could accommodate itself as may be called for in its function, rather than to have joined the ileum to the sigmoid and have had two long mesenteries to the both parts of the union, which would have increased the danger of twists or kinks at the site of union, and would have brought about an abnormal lay of the parts.

Dietaries in Sanatoria for Tuberculosis.—C. D. Spivak made a study of the dietary in the National Swedish Sanatorium, Englewood, Col. The quantity of food consumed by each person each day, counted by weight (excluding water taken pure and used in tea, coffee, soup, etc.), was 6.4 pounds. The number of calories each day for each person was 3,867.66, out of which the protein calories were 662.48, fat calories 1,676.60, and carbohydrate calories 1,521.52. Of the 662.48 protein calories 522.18 were derived from animal food and 140.30 from vegetable food. The amount of waste was insignificant, the greatest amount being eighteen pounds of cooked potatoes and a few pounds of cooked cereals, which would reduce the number of calories for each person each day by not more than ten. It was very gratifying to notice that there was almost no waste at all in bread, milk, and butter.

Septic Endometritis.—H. Weil notes that if the infection takes on the inflammatory type, as it usually will following early abortion, little can be done locally except to maintain drainage by dilatation, irrigation, and posture until such a time as the infection localizes itself in pelvic abscess, when this should be carefully and thoroughly drained through the vaginal vault. If, on the other hand, the disease assumes a toxemic or septicemic type, and it will usually do this after late abortion or labor at term, then steps must be taken to prevent toxin absorption from the uterine cavity, for he has pointed out (1) the toxin laden and toxic nature of the lochia, (2) the absorptive power of the puerperal uterus, (3) the influence of absorption from this source in puerperal sepsis, and (4) the favorable results of frequent or continuous irrigations in checking this absorption. It is not to be understood from this conclusion that irrigations are advocated in all cases of sepsis, for it must be remembered that, as a rule, the curettage will of itself be sufficient to control the infection in the great majority of cases, but when for some reason or other this curettage fails, it is then, and only then, that the irrigation treatment is recommended.

Lavage of Duodenum.—M. H. Gross describes his method as follows: The patient swallows the duodenal tube weighted at the end by a carefully protected small silver ball to the mark of 45 cm. (ultracardial); the patient having now assumed a recumbent position on his right side, the small ball tends to, and does, gravitate toward the pylorus, drawing the tube with it, which it is allowed to do to the mark of 60 cm. (pylorus). Next the tube is carefully pushed on, practically yielding to the gentle traction of the ball, until the mark, 75 or 80 cm., has been reached. After from twenty to thirty minutes the first aspiration is made, which will often yield gastric contents mixed with duodenal contents of acid reaction (Congo), but sometimes, even at this distance, pure characteristic alkaline duodenal contents. The tube being safely lodged in the duodenum, the desired lavage can be effected with the patient in a sitting or recumbent posture by simply pouring the fluid (as is done in gastric lavage) into a glass funnel attached to the outer end of the tube, which is wide enough for this purpose; or by direct filling of the glass ball, the "receptacle." The latter method is indicated if the fluid does not flow off rapidly enough, in which case light blowing through the "mouthpiece" will ensure the desired result.

When Sedatives Are Tonic.—W. F. Waugh refers to cases in which the sense of weakness is due to excessive irritability of the nervous system, the steadying of which by the bromides immediately produces a sense of "feeling stronger." Many times he has made this observation, but in most cases the relief followed much smaller doses of bromide than are usually employed. Five grains of sodium bromide repeated hourly for three doses, but no more, and not that if relief comes with two doses, or one, give finer results than excessive bromism. In this hyperesthetic condition denominated erethism the morbid impressibility is such that comparatively slight irritations will induce a discharge of nerve force, and the patient is never able to accumulate a store of forces.

X-Ray in Cancer.—Rudis Jicinsky concludes that *x*-rays have selective power for such irritated and weakened cells as he characterizes those of cancer, and in some individual cases, when given in time, will give objective and subjective results. They will prepare the field of infiltration for operation, in every case of malignant character, relieve suffering and prolong life, and in the most desperate cases not only the pain but also the odor of the discharge are checked right from the start, and the patients are comfortable, even able, to some extent, to attend to their social duties. The electrochemical action of the rays produces a yellowish, honeylike exudate in the open lesions proper, and the treatment has robbed death from cancer of its horrible, painful, and offensive elements.

Typhoid Fever and Parotiditis.—R. E. Coughlin summarizes the report of a case as follows: First, there was a child, thirteen years of age, presenting all the signs and symptoms of acute appendicitis. Second, an exploratory operation showed the appendix firmly bound down by adhesions, with the mesenteric glands so swollen and enlarged as to suggest either typhoid fevor or peritoneal tuberculosis. Third, the development of single and later double parotiditis, which by a few authors is regarded as a very unfavorable symptom when occurring in the course of any acute general disease because of the probability of severe infection. Fourth, the fact that the parotiditis was double instead of single, which is the common type when accompanying any general disease. Fifth, that the double parotiditis cleared up without suppuration, which is rather unusual when parotiditis is a complication. Sixth, the typical typhoid course of the disease as it is seen in adults, accompanied by repeated hemorrhages, which are uncommon in children. Finally, the complete recovery of the patient after a protracted course covering ninety-seven days.

Urethral Instrumentation.—G. Greenberg states that when a physician introduces an instrument, even a catheter, into the urethra, he should have a thorough working knowledge of its application and its indications; and above all, he should have a definite object in view. While an instrument may have a beneficial effect when judiciously and opportunely applied, it will be deleterious when injudiciously used. A good deal of our success depends on a correct diagnosis, and this can be reached only after a thorough and painstaking history and examination of the patient. Another important point to bear in mind is the importance of asepsis and antisepsis, which is just as necessary for the success of urethral surgery as it is in general surgery, for after treating the patient for a length of time without a distinct improvement, the physician is often disappointed with results. It is, in fact, surprising that results of indiscriminate instrumentation are not more disastrous; this, however, can be accounted for by the kindness of Nature and the resistance of the patient. Instruments often carry infection from one patient to the other, if not properly sterilized, and from one part of the urethra and its adnexa to another.

Occlusion of Arteries with Metallic Bands.—By R. Matas and C. W. Allen. See MEDICAL RECORD, Vol. 77, page 1109.

Uterine Arteriosclerosis.—By S. A. Chalfant. See MEDICAL RECORD, Vol. 77, page 1032.

Aspirating Device.—J. H. Williams describes his device, which is an addition to the siphon used by dentists: the water, passing rapidly down the specially constructed metal tube attached to the faucet, produces suction in the rubber tubes and glass container. The blood, mucus, and some air in the patient's throat pass into and through the hard rubber mouth attachment, and are continued along the rubber tube to the glass container, where the blood and mucus are deposited, the air going on through the second tube from the container to the faucet, and out with the passing water. In all operations within the mouth or throat under general anesthesia, especially the removal of adenoids and tonsils, this apparatus is designed to keep the field of operation clear; to obviate the necessity of sponging, thereby reducing the number of assistants, and also to preclude the possibility of the patient aspirating or swallowing the exuded blood, etc.

Cough During Auscultation.—F. C. Smith states that the râles most important in diagnosing pulmonary tuberculosis are not heard during ordinary respiration. A light cough at the end of expiration may reveal, during the inspiration following, fine adventitious sounds, indicating a lesion, before the Röntgen rays will cast a shadow of it, long before the percussion note is impaired, and frequently before the normal respiratory murmur is modified. This simple expedient is described in most textbooks on physical diagnosis, and is resorted to by all expert clinicians. Its omission is even noticed at once by an experienced patient. But it is believed that the average busy doctor sometimes neglects it.

Pellagra.—B. R. Tucker describes the conditions in pellagra and gives an elaborate analysis of the symptoms, etc., in fifty-five sporadic cases. From his analysis he deduces the following: 1. Pellagra may occur at any age, and, while no race is free from it, the whites are most affected, and it is sometimes seen among those of good hygienic and social surroundings. The cases were scattered, not occurring in local epidemics, and most common in rural districts, the majority of cases occurring in the spring and early summer. The gastrointestinal symptoms are first in order before the skin or nervous manifestations. Maize products cannot be considered the sole cause, and bad habits or previous existence of chronic disease do not seem to increase the liability, and exposure to the sun does not account for the cutaneous lesions. These latter always affect the back of the hands and are symmetrical. Stomatitis is almost constant. The nervous and mental symptoms are not conformable to any one form of disease and form no distinct clinical entity. The special senses are only occasionally affected. The eye symptoms are not pathognomonic. Emacition is practically constant, and a moderate anemia is found in most cases. Pellagra is not in itself a febrile disease and, when fever occurs, it may frequently be accounted for by a complication. The heart, lungs, and genitourinary organs are not generally affected, and examinations of the urine, feces, and blood show nothing pathognomonic. The cause is unknown, and in the cases examined no parasite or toxin has been isolated. The disease is not communicable by ordinary contact. The order of involvement seems to be, first, the digestive tract; second, the cutaneous surface, and, third, the nervous system. There are two forms, the acute or fulminating,

and a chronic, often remitting, type. Remissions occur in over half the cases, but death frequently occurs in the first attack. Probably 50 per cent. of the patients die during the first two years. It cannot be said in the cases studied that any patient is cured, as apparent cure may be only a remission. No specific remedy has been found and the treatment is unsatisfactory. Possibly hexamethylenamin may have some curative properties. He also sent out inquiries by mail to various institutions, and received replies reporting a number of cases, of which 226 were fatal and 157 had, at time of reporting, no symptoms of the disease. He does not think it possible that a disease so serious and so striking in its characteristics can have existed in the United States for more than a few years past without recognition. It calls, therefore, for a thorough investigation, and its cause should be searched for till found. He suggests a climatic treatment, as some patients seem worse in warm weather and even on warm days in winter. He tried hexamethylenamin in five cases, two of them very severe ones, and such prompt and striking improvement followed the administration that, though the number was very small, he thinks that it deserves further trial.

The Making of a Surgeon.—G. W. Guthrie asks if the question of special fitness should not be raised in the appointments of hospital staffs by the managements of such institutions. At present the reasons that actuate them are various. Sometimes they are political and sometimes from the desire to have as large a force as possible and to make frequent changes. The question of special ability is rarely raised. All over the country there are men acting as surgeons for hospitals that never do any surgery elsewhere and never go away to learn from real surgeons how the work should be done. The notoriety obtained by successful surgeons captivates them and they neglect the consideration of the triumphs of internal medicine and still greater need of skilled physicians. He gives the reply of a number of the leading surgeons of the country as to the qualifications needed for surgeons, received in answers to letters addressed to them, and from these he draws his conclusions as to the essentials. First, the man. Some men are not fitted by Nature for the work, and Nature's equipment for surgical work is to be considered. The surgeon must be a handy man and must be mentally fitted to weigh all the evidence and come to the correct conclusions in his diagnosis. He must be a normal man mentally and physically, healthy, tireless, and conscientious. The golden rule is nowhere more applicable than in surgery As to his educational requirements, the curricula of the best medical colleges leave little to be asked by the thorough student in the present state of our knowledge. After graduation the question arises, Is he then prepared for the work of a surgeon? A term of one or two years in a general hospital giving a wide experience in medical and surgical work under the direction of competent chiefs is requisite, and many eminent authorities urge that, in addition to this hospital practice, several years in private practice are necessary, as the conditions are very different in private practice and in hospital practice. But before he should undertake important operations the opinions of those competent to judge, which are practically in agreement in the letters quoted, insist on a period of preparation as assistant to a good surgeon or surgeons. Were surgery nothing more than a trade, the apprenticeship would have to extend over several years; but surgery is more than that. Finally, several of the eminent men quoted make it a point that the surgeon should observe the work of his fellow surgeons. Those who have acted on this advice know what the benefits of such a course are.

Uncinariasis in Mines.—H. Gunn concludes that hookworm disease is endemic in certain mines in California; from 50 to 80 per cent. of those working in these mines are infected; the infection undoubtedly is present in practically all of the gold mines of California, and in those just over the border of Nevada. In conclusion, he expresses the belief that hookworm disease is endemic in many mines in various parts of the United States. In many of the so-called cold mines, portions are found where the temperature is constantly high and moisture is present. In all probability most of the mines of this country have been exposed to infection, for in nearly all of them may be found Hungarians, Austrians, Italians, or Cornishmen, some of whom are certain to have brought the infection with them from the mines of their countries.

Splenic Abscess.—A. M. Fauntleroy reports a case of this condition. An operation for gangrenous appendicitis has been performed. The post-mortem findings clearly indicated a widespread pyemic condition, with a primary focus in the spleen, and it would seem that the lesson to be learned from the history and findings in this case is that the splenic condition could only be diagnosed by exclusion. Systematic writers on this subject invariably refer to pain in the left side high up. At no time was there the slightest pain in this region, nor could the spleen be palpated. It is believed that the splenic abscess resulted from the gangrenous pyogenic condition of the appendix and cecum.

Idiosyncrasy to Aspirin.—C. Graham reports a case of edema of the eyes, nose, and mouth, rapid pulse and respiration, following the taking of five grains of aspirin

Drainage in Otitis.—M. D. Stevenson describes the use of cylindrical gauze and cotton drains in discharging ears.

Preparation of Tincture of Guaiac.—H. W. Soper states that since Weber's modification of the guaiac-turpentine test for occult blood in the feces and stomach contents, every writer on this subject has uniformly insisted on using only the freshly prepared tincture of guaiac. Many have advised that the interior of a fragment of guaiac should be selected. During the past two years the author has experimented with older tinctures, controlling the reaction by the freshly prepared tincture. To his surprise, he found no evidence of deterioration; in fact, he often observed a more sensitive reaction from the older tinctures.

Removal of Adhesive Plaster.—E. J. G. Beardsley mentions the difficulty often experienced and the pain and discomfort to the patient, in the removal of adhesive plaster, especially over hairy parts. He accidentally discovered that oil of wintergreen, applied directly to the plaster, spreads throughout the adhesive material and causes it to come away readily and painlessly. When extensive areas are to be removed the application of an ointment of adeps lanæ hydrosus, with 10 per cent. of oil of wintergreen incorporated, is even more useful than the oil alone.

Serum Treatment of Graves' Disease.—A. E. Taylor reports the results of experiments with Beebe's antithyroid serum on animals (Belgian hares), carried on at the University of California several years ago. These animals were subjected to increasing doses of the thyroid protein prepared according to the published directions of Beebe, until the serum of one of them, on being tested, gave a good precipitation with the material used in the immunizations. The only variation in the technique was the adding of trikresol for chemical sterilization. The results were negative, and for this reason Taylor did not publish them at the time, not wishing to throw doubt on positive statements so long as the question was one of experimentation. Since then, others have published negative results, however, and he therefore offers these. P. K. Brown of San Francisco tried this serum in several cases of active Graves' disease with similar negative results. Specific reaction gradually decreased until within a year it ceased altogether. Evidently the precipitating protein is denatured on standing, probably through a reaction of hydrolysis.

Vaccine Treatment of Rhinitis.—C. C. Grandy reports a case of severe chronic influenzal rhinitis treated by vaccine therapy with a culture of autogenous influenza-like bacilli from the discharge, resulting in great improvement. The bacillus was not motile and was regarded as an influenzalike bacillus because it was small, Gram-negative, and grew in symbiosis. The vaccine was prepared by heating the bacillus at 56° C. for thirty minutes. Three months later the patient was in the best of health, but still had a small discharge.

X-Ray Examination of the Bladder.—J. M. Garratt suggests the use of bismuth solutions for radiographing the bladder. It is not always easy to use the cystoscope, and in some conditions it may be impossible or actually dangerous. The radiograph, moreover, would, he thinks, more readily give the information required in many cases. He recommends, after washing out the viscus, the injection of the bladder with Haenisch's solution used in the large intestine, viz.: Bismuthi subcarbonatis, 50 grams, kaolini, 250 grams, aquæ dest., 1,000 grams. Take at least two radiographs, one in the prone position with the anode centered over the sacrococcygeal articulation; this should be the standard exposure for the bladder; the other can be taken at any desired lateral or dorsal angle. The proper angle having been found, stereographs would be of great value. The bismuth solution can be removed by irrigation after the exposures are allowed to pass off naturally. The danger of poisoning by absorption is practically *nil*.

Ureterotubal Anastomosis.—A. Werelius states that he is endeavoring to anastomose ureters with the tubes, and also to implant them into the uterus. The immediate results in dogs seem very promising. Besides a trial dog, thus far only two dogs have been used of a coming series.

Choroid Plexus.—S. P. Kramer, after mentioning the fact that the choroid plexuses of the cerebral ventricles are the secretory organs for the cerebrospinal fluid and describing their anatomy, describes and gives tracings of experiments on dogs demonstrating the depressant action on blood pressure of a filtered extract of these plexuses when injected into the veins. The jugular vein was the one employed, and the extract was taken from the brain of a patient dying from pneumonia, and from dogs. The suggestion occurred to the experimenter that possibly in certain cerebral disorders, especially those associated with hypersecretion of the spinal fluid, there might be an excess of this depressant, and experiments were made with cerebrospinal fluid obtained by lumbar puncture from human subjects who were suffering from such diseases. The indications obtained in these cases are that the fluid was supercharged with the depressant. That obtained from a patient who had recovered from mild delirium tremens did not have such characteristic effects. It also occurred to the author that the secretion of the pituitary body would also enter into the cerebrospinal fluid in the ventricles. This pituitary secretion, as is well known, causes a marked elevation in blood pressure, and an extract of the infundibular lobe of the sheep's pituitary gland was mixed with the chorioidal extract and injected into a dog. The tabulated results show that they counteract each other, though incompletely. It is evident, he says, that these two principles, which, one presumes, are poured into the cerebrospinal fluid, have a tendency to counteract each other in so far as their effect on the circulatory apparatus is concerned. It will be a matter for future investigation to determine, if possible, under what circumstances one or the other gains the supremacy. A further report on the nature of the chorioid "depressant" is promised.

Optimistic Therapeutics.—G. M. Niles states that, while volumes have been written concerning the psychic attitude of patients and their treatment accordingly, but little has been said about the psychic attitude of the physician who has to shoulder the problems these patients present. He thinks that the therapeutic nihilism of the German school has infected the medical profession too seriously. The patients are not interested in skilled diagnoses so much as they are in what will make them well, and it is the physician's duty, and only giving the patient his right, to encourage an optimistic feeling in the patient. It is only in the rarest and most exceptional instances, or when the patient is actually *in articulo mortis*, that we have the right to shut the door of hope. He would not accept the authority of any man or set of men to say that any disease or complication of diseases would make his own case hopeless, and he claims the same right for his family, and he asks why he should not himself be fired by the same optimism in the treatment of his patients, no matter what the outlook may be. What the patient comes to the doctor for is treatment and encouragement, and he has a right to get it. Pessimism is not the mood for a physician to cultivate.

Some Points in the Diagnosis of Orbital Disease. J. S. Hosford.
Transverse Fractures of the Patella, Without Separation of the Fragments. A. E. Johnson.
A Case of Congenital Pulmonary Stenosis, with Special Consideration of the Nature of the Secondary Blood Changes. F. P. Weber and G. Dorner.
The Intravenous Method of Treatment of Syphilis with Salvarsan (606) with a Convenient Apparatus for Such Administration. H. W. Bayly.
"Nodular" Fibromyositis, an Everyday Affection and Its Identity with So-called Chronic Muscular Rheumatism. W. H. M. Telling.
The Influence of Chloroform when Repeatedly Administered in Small Doses. G. H. Clark.

Diagnosis of Orbital Disease.—J. S. Hosford states that inflammation of the cellular tissue of the orbit may be due to blood states and metastatic inflammation. It is commonest in children and the aged, but it is far more usually due, at all ages, to trauma and spreading inflammation from contiguous cavities, especially the nasal and accessory sinuses of the skull, the antrum of Highmore, from disease of the bones *per se*, from oral sepsis, especially Riggs' disease, or due to erysipelas or to carbuncle. With regard to trauma, it is surprising how trivial an injury will sometimes start a virulent orbital cellulitis; the opening of a Meibomian cyst has caused it, and it has frequently followed excision of the eyeball when there has been a conjunctival discharge, or panophthalmitis, at the time of the excision, which has terminated fatally. Of the troubles that cause difficulty in diagnosing whether there is true orbital cellulitis at all, acute purulent conjunctivitis, acute thrombosis of the cavernous sinus, and acute lacrymo-adenitis, of these the second, cavernous sinus thrombosis, is most likely to cause great difficulty where there is no present, but only past, external ear disease. The author has twice known the patient to be operated upon for orbital cellulitis when the cases have been those of sinus thrombosis. Here the diagnosis should not be difficult if one takes a larger view of the patient and does not confine himself to the swollen orbital contents. In the first place, sinus thrombosis is very sudden in onset, not very painful, if at all, in early stages; edema of the forehead and over and about the mastoid is nearly always present, and in one of these cases tapping the mastoid elicited pain and tenderness. Secondly, the chemotic tissue protrudes between the lids more than usual, and the skin of the lids is soft and supple. Thirdly, since the veins are blocked, and the only possible means of draining the eyeball is through the communication of the angular with the facial and through the sphenomaxillary fissure with the tributaries of the internal maxillary, one expects to find some symptoms altering or abolishing vision, as well as ophthalmoscopic signs, if the upper lid can be sufficiently elevated. Engorgement of the retina and blindness should always be searched for in orbital cases. There is a condition which, although not actually orbital cellulitis, yet is so intimately related to it that when you see it for the first time you are sure to

diagnose "orbital cellulitis"—and that is metastatic panophthalmitis. Of the slowly growing swellings of the orbit are mentioned chiefly chronic periostitis, abscesses, exostoses, gummata of the soft parts, and the cysts and new growths. Solid tumors of the orbit are much more deeply seated than the cystic. They are fibromata; lymphomata which are often symmetrical and associated with lymphatic nodules in other organs of the body; endotheliomata and sarcomata. Cystic tumors of the orbit include meningoceles and encephaloceles, dermoids, hydatic cysts, dacryops, and congenital cyst of the lower eyelid connected with the globe. The swellings in the orbit most likely to be confounded with the cysts in the early stages are the vascular tumors—the nevi and nevolipomata, and the arteriovenous aneurysm. Lacrymal gland tumors sometimes grow to a great size before they cause symptoms or physical signs.

Transverse Fractures of the Patella.—A. E. Johnson in bringing the subject of transverse fracture of the patella, without separation of the fragments, under notice thought it would give food for thought in many ways; pathologically the cases are interesting; the clinical picture is most striking and teaches us to hesitate very much before giving a definite diagnosis of a bone lesion without the help of the *x*-rays, and historically, in accounting for probably most of the cases of bony union which were recovered from the post-mortem and dissecting rooms before the days when wiring was the usual treatment. By far the most important point for the surgeon is the difficulty of diagnosis, and he must now realize that he is absolutely dependent on the *x*-rays in such cases. With regard to the frequency with which these cases occur, it is difficult to speak with certainty, and until it is the rule to examine all injuries of joints with the *x*-rays, we cannot say how many of these cases are being missed at the present time. The cases he describes occurred in the practice of the Middlesex Hospital in a period of thirteen months, during which time there were treated in all twenty cases of fracture of the patella. Failure in diagnosis may not only involve the surgeon in a suit for damages, but if the character of the injury be not realized by somebody else, an unusual strain may lead to great hardship for the patient, owing to separation of the fragments and the necessity of an operation which would otherwise have been unnecessary.

Congenital Pulmonary Stenosis.—F. P. Weber and G. Dorner report a case which may be regarded as an extreme example of cyanosis and polycythemia in an adult secondary to congenital heart disease. It shows that in these cases as in "splenomegalic polycythemia" ("erythremia"), not only the number of red corpuscles and the amount of hemoglobin per cubic millimeter of blood are greatly above the normal, but so also are the amount of hemoglobin (as measured by the oxygen capacity) and the volume of blood per 100 grams of body weight; there is, in fact, a condition of true plethora ("polyhemia") present, so that the degree of absolute polycythemia is much greater even than the degree of relative polycythemia. The secondary polycythemia in cases of congenital heart disease is seldom, if ever, rivaled in degree by the secondary polycythemia which sometimes, as is well known, occurs in chronic acquired valvular affections (of the mitral valve) and in adherent pericardium. It is more nearly rivaled by the marked secondary polycythemia occasionally associated with late stages of pulmonary emphysema, chronic bronchitis, asthma, old bilateral pleuritic adhesions, chronic interstitial pneumonia, and pulmonary fibrosis. The polycythemia in all such cases differs from the polycythemia (possibly of primary myelogenous origin) associated with chronic splenomegaly, which has been termed "erythremia," by the not infrequent absence of real cyanosis in erythremia, especially in its early stages. What prognostic significance can be attached to the secondary polycythemia in cardiac cases? In answer to this question, the authors state that just as hypertrophy of the walls of the heart is useful in so far as it compensates for mechanical defects in the valvular apparatus, so also is polycythemia useful in so far as it compensates for difficulties in the proper oxygenation of the blood and tissues of the body; but just as in cardiac valvular disease great hypertrophy of the heart indicates some grave defect in the valvular mechanism, so also an extreme increase in the number of erythrocytes in the blood points to there being great impairment of the normal process of oxygenation of the body.

Intravenous Injection of Salvarsan.—H. W. Bayly describes his method of administering salvarsan by means of intravenous injection.

Nodular Fibromyositis.—W. H. M. Telling concludes that all chronic rheumatism is essentially an exudative hyperplasia of fibrous tissue, probably inflammatory in origin, and the clinical characters of which depend upon the amount, persistence, and anatomical situation of such inflammatory exudate. It has a preference for certain fibrous areas, the frequency of ordinary lumbago testifying to this. The varying situation of such inflammatory exudate is well illustrated by the fact that most cases of sciatica are due either to pressure on the nerve by a nodule or to infiltration into its sheath. Many cases of supraorbital neuralgia are similarly explained. The one almost constant symptom which results from this fibrositis is pain. These infiltrations are painful when they are pressed upon, and if vigorously rubbed they swell up and the pain is greatly increased. This local pain on pressure is practically the diagnostic feature of these cases. The author draws attention especially to the following points: (1) the extreme development as to size and hardness of the more severe indurations; (2) the extreme character of the pain that may result from indurations of every kind, and (3) the secondary nervous phenomena, or states of acute or chronic invalidism which may supervene as results of the extreme or persistent pain. It is difficult to realize, short of actual experience, the severity of some of the cases. A further point, and one upon which he places the greatest possible stress, is the extremely wide range of the painful manifestations, and the serious, yet at the same time avoidable, diagnostic errors for which this is responsible. The causes of this condition are as follows: By many rheumatism is supposed to be one. That true rheumatism does cause fibrous nodules is familiar, and the remarkable and rapid way in which they disappear is a sufficient answer to those who cavil at the curability of the indurations and nodules of chronic fibrositis. The author is unable to accept the view that chronic rheumatism, as ordinarily met with, is a sequel of true original rheumatic fever, or, indeed, that it occurs with any frequency in genuine rheumatic subjects. Influenza is responsible for a certain number of the cases; a fact of clinical importance. Exposure to cold and wet is very frequently responsible. His own feeling is that disturbances of the gastrointestinal tract, such as oral sepsis, flatulent dyspepsia, chronic constipation, etc., all conditions leading to the production and absorption of toxins, play a somewhat important etiological rôle. Trauma certainly explains some cases, either in the form of frequent slight traumata from overexertion, as in athletes or laborers, especially when coupled with exposure, or in the form of local injury. This undoubtedly gives rise to the condition, and is a point which is well worth bearing in mind in regard to certain cases occuring under the Employers' Liability Act.

Influence of Chloroform in Small Doses.—G. H. Clark states that chloroform repeatedly administered by the respiratory passages, subcutaneously, and by the stomach in small doses rapidly kills rabbits. The liver shows degeneration of the cells sometimes so marked that the whole center of the lobule is broken down into débris.

The cells in the center of the lobule are early affected, those further out later. Fat is always present, generally in large quantities. The kidney suffers to some extent, but relatively more when the chloroform is inhaled than when injected or given by the stomach. Fat is occasionally found in degenerated cells. The spleen shows intense congestion, the sinuses being packed with red blood corpuscles. Along with the red corpuscles, an orange-colored pigment is generally present which reacts to the stain for iron. A large number of very large phagocytes are present in most cases. The average weight of the spleen is 0.46 gram heavier than the controls when chloroform was inhaled, and 0.59 gram and 0.17 gram heavier when injected and when given by the stomach, respectively. Degenerative changes were observed in the cardiac muscle. Fat was not observed in any of the hearts examined.

Cardiac Arrhythmia. A. J. Rex-Blake.
Theory and Practice in the Treatment of Pulmonary Tuberculosis. W. C. Bosanquet.
A Series of One Thousand Inoculations, Chiefly in Private Practice. H. W. Crowe.
Typhoid Infection. J. A. Mills.
Myasthenia with Enlargement of the Thymus Gland. J. O. Symes.
The Antihemolytic Action of Arsenic. J. A. Gunn and W. J. Feltham.

Cardiac Arrhythmia.—A. J. Rex-Blake states that analysis of the causes of irregular action of the heart shows that they are very various, but that they may be divided up into two great classes: (1) Those arising within the heart and due to changes in the state or nutrition of its walls, or of the Purkinje cells that form the bundle of His. (2) Those arising outside the heart, and due either to alterations in the nervous impulses coming to it from the central nervous system, or to changes in the ease with which the blood enters or leaves it. One may take it as proved, then, that the rhythmical impulses to contract start in the sinoauricular area of the heart and travel to the ventricles by way of the bundle of His under normal circumstances. Cardiac irregularity may occur in healthy people. The next arrhythmia to which the author calls attention is the respiratory irregularity. It is noted that in the majority of normal persons inspiration causes a quickening of the pulse, and expiration a slowing. This respiratory arrhythmia of the heart is oftenest and best seen in children and young people, and is worth mention because it is sometimes so marked and leads to so great an irregularity in the pulse that the patient is labeled "heart disease," and treated accordingly. Neurogenic arrhythmias, the third group of the reflex arrhythmias, are still commoner than the respiratory. In certain patients almost any severe mental or sensory stimulation may bring on an attack of rapid or intermittent action of the heart. This is particularly so with nervous and excitable people. Toxic causes of irregular heart action are the immoderate use of tobacco, tea, coffee, and alcohol. Arrhythmias are seen with meningitis, intracranial tumor, and in any condition increasing the intracranial pressure, and the heart's action tends to be slower and more intermittent as the pressure increases; this is, no doubt, due to the increased stimuli descending from the vagus nucleus. Among the small group of vascular arrhythmias it is noted that pericardial adhesions by preventing the venous blood from reaching the heart in proper quantity cause slowing of the heart and, if it happens during inspiration, will produce what was called the "paradoxical pulse" by Kussmaul (1873), in which the pulse is slowed—and even a beat or two may be dropped—in inspiration. It is to the intracardiac group of arrhythmias that the more serious and more frequently fatal cases belong. In considering the irregularities caused by functional disorders of the bundle of His, the author notes that digitalis, when pushed, may cause irregularity of the heart by lessening the conductivity of the cardiac muscle, and so preventing the normal passage of the impulses to contract. If the bundle of His is seriously interfered with or destroyed by organic disease—for example, fibrosis, gumma, or other new growth—absolute heart block is likely to result, with slow or irregular action of the ventricles. In typical instances of heart block the clinical picture produced is that of Adams-Stokes disease, or slow pulse—28 to 35 beats a minute—combined with syncopal attacks, when for a few seconds the heart ceases to beat at all, as it does from time to time. The diagnosis of this form of irregular pulse depends upon its occurrence in the form of a well-marked syndrome like the Adams-Stokes disease, on the one hand, and on the other upon the securing of evidence, best by means of jugular and carotid tracings, that the auricles and ventricles are not contracting in uniform succession, but independently of one another. Another form of irregularity is the interpolation of extra beats for extra-systoles into the otherwise regular action of the heart. The extra-systole is a premature systole due to abnormal stimulation of the heart, and is followed by an abnormally long diastolic period. Extra-systoles occur in a variety of organic diseases of the heart, and probably always indicate myocardial disease or overstrain. Thus they may cause irregularity of the heart in patients with high blood pressure and renal disease in whom compensation is beginning to fail, when they are perhaps due to failure of the left ventricle to empty itself in systole, the residual blood acting as an abnormal stimulus, making the ventricles beat again, but more feebly, before the normal auricular impulse has come down to the ventricle. Such an extra-systole, arising in the ventricle, is known as "ventricular." In patients with mitral disease and dilatation of the left auricle the dilatation may cause the occurrence of "auricular" extra-systoles in an analogous way. A very similar irregularity occurs in overstrain of the heart or in chronic myocarditis. Paroxysmal tachycardia belongs to the group of arrhythmias.

Treatment of Pulmonary Tuberculosis.—W. C. Bosanquet concludes that there is no specific remedy or universal mode of treatment for tuberculosis of the lungs. Neither tuberculin, nor rest, nor work, nor mountain air, nor a sea voyage, nor a sanatorium is an infallible remedy to be administered to all, as we give quinine for malaria or mercury for syphilis. One has to study the individual patient, his circumstances and his idiosyncrasies, and, armed with this knowledge, to try to raise his resistance to the bacillus and its poisons. Fortunately the human organism has considerable powers of resistance, if it is not debilitated by adverse conditions; and though one must, above all, endeavor to recognize cases early, before the disease has advanced far, yet even in advanced cases there is always hope of arrest of the disease or at least of a temporary reprieve and prolongation of life.

One Thousand Vaccine Inoculations.—H. W. Crowe reports the following results following the use of vaccines: Staphylococcus infections, 32 cases: cured, 28; improved 4. Streptococcus infections (septicemia, wound infection, nasal catarrh), 4 cases: cured 3, not improved 1 (nasal catarrh). Infections due to *Bacillus coli*, 6 cases: cured, 4; improved 2. Infections of the respiratory passages, other than tuberculosis, and caused by the pneumococcus, *Micrococcus catarrhalis*, the bacillus of Friedländer, and the bacillus of influenza: 8 cases; 7 cured, 1 not improved. Infection by the tubercle bacillus, 37 cases: 17 cured, 5 improved, 8 not improved, and 7 still under treatment. In the use of tuberculin, two points are noted. The first of these is that in the hands of the ordinary medical man there is grave danger associated with the exhibition of tuberculin in phthisis while patents are walking about and pursuing their ordinary avocations. It is only a matter of common sense after all. Tuberculin causes hyperemia, and the more hyperemic the lesion the more easily will a

dangerous autoinoculation be induced by exercise. True the cure may be through autoinoculations; but if autoinoculations be allowed to become excessive, as they will become excessive if tuberculin and exercise are combined, then inevitably will the disease extend. The second point is as to the length of time that it is necessary to continue treatment. The various diagnostic tests, such as those of Calmette and von Piquet, are not trustworthy guides on this question. Two excellent indications are the following: 1. The patient should be able to take 1-5000 T.R. without any effect noticeable, either in the temperature or in the opsonic index. 2. After sufficient exercise to cause thorough exhaustion there should be no sign of an autoinoculation; that is to say, that the opsonic index, a far more reliable test than any subjective sensations and many times more delicate than the temperature—the opsonic index should not fluctuate.

Typhoid Infection.—J. A. Mills attempts to explain the greater prevalence of typhoid fever in the autumn on the basis of the following factor: It is in autumn, when the grain has been gathered and as winter approaches, that rats and mice leave the fields and make for human habitations. One means by which they obtain entrance—as a matter of common observation—is by drain and sewage passages, especially if these be defective. (Rats themselves are apt to cause leakages and defects in improperly constructed sewage passages.) Granted the existence of people with actual typhoid, or of human typhoid carriers whose excreta is among the sewage, where the rats live, and which it is possible they devour, it is easy to see how millions of bacilli may be present on the body, feet, jaws, and tails of these rodents, whereby food and drink may become directly as well as indirectly contaminated.

Myasthenia with Enlargement of the Thymus.—J. O. Symes reports a fatal case of myasthenia, in which post-mortem examination showed enlargement of the thymus gland. With regard to the causation of the condition and its relationship to the status lymphaticus little can be said. Buzzard thinks the symptoms of myasthenia are best explained by assuming the presence of some toxic agent which has a special influence on the protoplasmic (as opposed to the fibrillar) constituent of voluntary muscle," and in this case the presence of numerous minute hemorrhages in the gastrointestinal tract was very suggestive of an infective process. The relation of such an infective process to the thymic alteration is not clear. There is no reason to think that this patient had at any time previously suffered from an enlarged thymus, but the death symptoms, asphyxia, and reflex cardiac failure are like those of status lymphaticus. One can only conjecture that the enlargement of the thymus and spleen were compensatory to some lymphoid exhaustion brought about by an acute toxemia, probably of gastrointestinal origin.

Antihemolytic Action of Arsenic.—J. A. Gunn and W. J. Feltham conclude from their experiments that arsenic, whether in the form of sodium arsenite or sodium arsenate, exerts on the red blood corpuscles an action antagonistic to that of certain hemolytic agents. The experiments, therefore, afford additional proof in favor of the view that a protective action on the formed red blood corpuscles against normal or abnormal hemolytic processes may, in part at least, account for the as yet imperfectly explained benefit which results from the medicinal administration of arsenic in blood diseases.

Berliner klinische Wochenschrift.

January 16, 1911.

Landry's Paralysis.—Dr. Bolten endeavors to bring up our knowledge of this affection to date. He concludes that this is sharply marked off from all others, is readily distinguished from polyneuritis and poliomyelitis by the absence of muscular atrophies, reaction of degeneration and sensory anomalies. The most typical cases, as shown by Westphal, Bernhardt, and Erb, rest upon an intoxication. The paralyses are the results of functional exclusion of the spinal and bulbar centers, and are not due to destructive anatomical changes. The toxin seems disposed to leave the sensory neuron alone and devote itself wholly to the motor neuron, although it does not appear to damage the latter. In all cases with degeneration-reaction and muscular atrophies we have, as already stated, to do with rapidly developing polyneuritis or to a parenchymatous poliomyelitis. In regard to therapy some cases may benefit. The cerebrospinal fluid is loaded with toxins and must be replaced by a harmless liquid. Some 40 c.cm of cerebrospinal fluid are withdrawn and about 30 c.cm. saline infusion substituted. The treatment is repeated about six times in eight days; so that in all 600 c.cm. of the toxic spinal fluid are withdrawn and replaced by 540 c.cm. physiological saline infusion. It does not follow that all cases can be so quickly reached.

Otology in Berlin.—Passow in the course of a brief controversy on the history of otology in Berlin quotes from the "Dictionary of Prominent Physicians" that E. Dann was the first dozent of this specialty in the University. This cannot be proven but is highly probable. But the first to hold lectures on the subject was doubtless Jüngken. The two men were near contemporaries—Dann a practitioner, who graduated in 1830, while Jüngken was lecturing during the session 1830/31. Dann wrote on the ear but was also interested in pathology. By 1842 both men dropped out of otology and it was not until 1847-48 that Graefe added this specialty to ophthalmology, surgery, and dentistry.

Diagnosis of Cancer of the Stomach by Means of Fischer-Neubauer's Method of the Splitting of Tryptophan.—There were not wanting earlier studies of autolytic enzymes in cancer, but the two authors above quoted sought for an albuminous derivative which would be characteristic of the action of such an enzyme. Such a substance was found in glycyltryptophan, the peptid-like combination of an amino acid. It is not formed save from the gastric juice of the stomach. The reaction is characteristic. The glycyltryptophan is exposed to the suspected juice and some time allowed for digestion. The addition of bromine, either vapor or solution, liberated the tryptophan. No other substance has yet been found to give this reaction.

Münchener medizinische Wochenschrift.

January 17, 1911.

The Active Substances in the Uterus and Ovary.—Schickele states that the characteristic action of the expressed juice and extracts of the ovary, corpus luteum, and uterus consists (1) in an inhibition of blood coagulation in vitro. (2) When intravenously injected an intense lowering of the blood-pressure results as a result of vascular dilatation, often with distinct delay in the coagulability of the blood. (3) In the appearance of twitchings and at times marked spasms with partial confusion. With still stronger action the respiration and blood are both slowed, death rapidly supervening. (4) In addition to the preceding spasmodic action many animals show intestinal contractions, with expulsion of feces and urine.

Prognosis of Pueperal Psychoses.—Jolly, after an extensive statistical treatment of this subject, emphasizes his belief that certain forms of psychoses not independent of the reproductive cycle do not come under clinical observation. These are chiefly manic and melancholic states of the transitory type, which are revealed by anamnesis or do not seem cases for treatment. These occur chiefly during pregnancy and lactation and terminate favorably.

Here belong the shortlived attacks seen during labor itself with the picture of acute hallucinatory confusion, or twilight states with complete amnesia. These usually subside after labor. For prophylaxis of the puerperal psychoses proper, such as come under treatment, melancholia persists longest with an average duration of thirty-six weeks, while all psychoses collectively last for about twenty-six weeks only.

Transmission of Antipyrin Supersensitiveness to Guinea-Pigs.—Klausner writes anew on this subject but appears to have little advance in his conclusions. He states that it is a genuine anaphylaxis, in which respect it has not yet been shown for the transmission of quicksilver idiosyncrasy and veronal idosyncrasy. He thinks the latter cases may represent something different containing no inherited element, but a temporary acquired idiosyncrasy to a drug when given in normal doses. This idiosyncrasy may result from cumulation, from a temporary state of susceptibility, etc.

Deutsche medizinische Wochenschrift.

January 19, 1911.

Artificial Pneumothorax.—Forlanini of Pavia reaches the following conclusions from his personal labors in this field. Artificial pneumothorax can cure pulmonary tuberculosis. The cured lung tissue can, if its spared portions again expand as far as the thorax and regain their former function. The prognosis naturally depends on the earliness of the operation. Yet even more advanced cases may be saved. The scars of the older lesions, the overstretching of the parenchyma, the bronchial deformity, etc., give rise to an unusual auscultation picture, and the function of the lungs may be rendered difficult. The pleura may not close up, and it may be necessary to repeat the operation. But in persistent pneumothorax it is easy to set up fresh pleurisy. The stretching again of the healed lung and the restoration of its function make possible the necessity of a second operation. While bilateral pneumothorax is indicated in theory, we have no facts to base an opinion on.

Salvarsan in Malaria.—Iversen and Tuschinski have studied this subject in the Caucasus after the somewhat questionable results obtained in tropical malaria. The authors' material seemed to comprise all forms of the disease. They find that a dose of 0.5 intravenously injected exerts a naturally specific action on all kinds of malaria parasites. In the tertian form the parasites leave the blood in from twelve to forty-eight hours and relapses cease. In the quartan form the action is not persistent, even if 0.8 is injected. In tropical malaria the therapeutic effect is short lived, even in high doses. The annular parasites soon return to the peripheral blood. The semilunar parasite does not disappear but shows alterations in form. In certain cases of tropical malaria, the condition actually becomes worse in all respects, *i.e.* the initial improvement is followed by an aggravation of symptoms. Generally speaking the experience of the authors does not differ from that of others in this field.

Successful Treatment of Chorea Minor with Salvarsan.—The known effects of arsenical preparations over chorea minor suggest the use of salvarsan in this affection, so that von Bokay has tested the remedy chiefly as a matter of record. But one case was tested, and the result was very satisfactory despite the fact that he knew nothing of the nature of the disease. The author injected 0.20 neutral arsenobenzol emulsion under the skin. Relapse occurred from time to time but the malady yielded in good season. The patient afterward took 178 drops of Fowler's solution as an after cure. A small necrotic area formed at the site of injection.

Ischias Scoliotica.—Plate concludes from a well illustrated study that in ischias scoliotica the disease is limited to more or fewer of the nerve roots. Through the intermediary of numerous anastomoses a transition to the lumbal plexus regularly occurs, whereupon a neuralgia of the sensible branches of the sensory muscle twigs of the iliopsoas occurs. In consequence the pain extends along the whole of the latter muscle which cannot be fully extended. The hip being bent it cannot serve as a support. The shortening of the leg affects the angle of the pelvis. To balance the body a scoliotic attitude must be maintained. In addition to the sciatica the myalgia of the ileopsoas must be treated.

Hemorrhagic Appendicitis.—Bassel reports a case of this condition in which the hemorrhage into the appendix appeared to be an old one, and the clots contained disseminated bacterial foci.—*Province Médicale.*

Excretion of Chlorides in Cardiac Dropsy.—Lakin finds that NaCl retention is in most cases secondary to water retention in cardiac edema, and that urea retention is probably to be similarly explained; but in certain cases it seems likely that salt-retention plays a more important part, and is the cause, rather than the effect, of the dropsy. In support of this are the following facts: the beneficial effect in some cases of salt-free diet; the very exceptional degree of salt retention in some cases; and the association in these cases of such extreme salt retention, with a relative inspissation of the blood.—*The Medical Chronicle.*

Tuberculosis of the Hip Joint.—Steinhardt, after giving as the only true cause of this affection its specific microorganism, describes the various predisposing causes and very especially the bad social and economic conditions which lower the general vitality. The presence of the disease in the wealthy is chiefly explained by the abandonment of hygienic rules. The disease probably gains its entrance through the respiratory and gastrointestinal tracts. The chief symptoms are: limping, limitation of motion, rigidity, night cries, favoring of the affected leg, which accentuates the limping, and the shortening, muscular atrophy, and spasms. The author emphasizes the great value of an early diagnosis, which can be arrived at through the following points: a limp which develops without apparent cause, pain in the knee, limitation of motion, muscular atrophy, night pains, positive tuberculin reaction, positive *x*-ray, deformity, and distortion of a slow and gradual development. Prognosis depends on the general conditions and an early diagnosis. The prophylaxis is all-important. Treatment chiefly consists in favoring the efforts of Nature to cure the process.—*Crónica Médico-Quirúrgica de la Habana.*

Bad Results of Hypoalimentation in Nurslings.—Luigi Concetti thinks that we often credit to hyperalimentation troubles in infants that are really the result of decreasing the nutrition given the child below the amount necessary to sustain life properly. Troubles then develop that are really the result of starvation. This fact not being recognized the food is still further diminished until death ensues. The symptoms that appear in these cases are similar in some ways to those of hyperalimentation; they are vomiting, thin, green stools, sleeplessness, and extreme restlessness. Calming medicines have no effect on the cries of the infant. Digestives, laxatives, and astringents are alike useless. Death often occurs in convulsions. If more food be given these infants will recover. This condition may occur in breast-fed children on account of a small amount of secretion, or of the inability of the child to draw milk from a badly formed nipple. Histories of such cases are given by the author. The vomiting is due to a spasmodic contraction of the stomach on emptiness. In such cases the author makes use of a polyfermentive digestive, a concentrated hydroalcoholic solution of pepsin, pancreatin, amylase, lecithin, hydrochloric, and lactic acids.—*Rivista di Clinica Pediatrica.*

Book Reviews.

Tropical Medicine and Hygiene. By C. W. Daniels, M.B. (Cantab.), M.R.C.P. (Lond.), Director London School of Tropical Medicine, Lecturer on Tropical Diseases London Hospital, Assistant Physician Albert Dock Hospital, Seamen's Hospital Society, formerly Director Institute for Medical Research Federated Malay States, Member of Royal Society Malaria Commission and in the British Guiana and Fiji Colonial Medical Services. With a chapter on Snakes by A. Alcock, C.I.E., M.B., F.R.S., I.M.S. (retd.). In three parts, with colored and other illustrations. Part II: Diseases Due to the Metazoa. New York: William Wood & Company, 1910.

The first part of this work was noticed in the Medical Record of July 16. The present volume is devoted to diseases due to the metazoa, and will be found a valuable adjunct to any textbook on Practice of Medicine. The work is liberally illustrated, and the practitioner will find the subject of intestinal parasites and filaria well handled. An introductory chapter discusses some of the difficulties of classification and nomenclature, and there is a useful *résumé* of the prophylactic measures to be adopted. Besides their manifest value to physicians in the tropics, these volumes fill a useful place as being midway between the works on zoology and the somewhat scant space devoted to these diseases in the standard works on Practice.

Practical Nursing for Male Nurses in the R. A. M. C. and Other Forces. By Major E. M. Hassard, R.A.M.C., and A. R. Hassard. London: Henry Frowde, and Hodder & Stoughton, 1910.

Although written for the nurses of the British Army, this little volume is deserving of a very much wider recognition, and it is most cordially recommended to all nurses and to all who are interested in the education of nurses. The title of the book exactly indicates its contents, for it is "practical" throughout, and contains nothing that a good nurse does not need. We have read the book through with much interest, and it is one of the very few books on nursing (or anything else) that we could wish to have been longer. The subjects treated in the volume are: Bed making; washing of patients, sponging, baths; observation of patients; local application of heat; Leiter's tubes, ice bags; leeches, blistering agents, caustics; enemata, catheterization; administration of medicines; the respiratory system, atmosphere, ventilation; nursing of tubercle, pneumonia; artificial respiration, asphyxia; food in its relation to the body; prevention and care of bed sores; poisons, snake bite; rheumatism, some heart and liver cases; nursing of fever cases; malaria; enteric fever; other infectious fevers; plague; cholera, dysentery; the surgical nurse and surgical technique; lotions and irrigations; hemorrhage, shock; wounds, frost bite; head injuries; septic cases; preparation for operation, and after-care; fractures, splints; sprains, dislocations; ear, nose, and throat; eye cases; rectal cases; mental nursing, delirium tremens; various details, and cleaning. The whole is well covered in 334 small pages; the language employed is simple and direct; there is no attempt to convert the nurse into a diagnostician, physician, surgeon, or bacteriologist; and the comfort and welfare of the patient are never forgotten.

Applied Anatomy. The Construction of the Human Body, Considered in Relation to Its Functions, Diseases, and Injuries. By Gwilym G. Davis, Associate Professor of Applied Anatomy University of Pennsylvania, M.D. Universities of Pennsylvania and Göttingen, Member of the Royal College of Surgeons of England, Surgeon to the Episcopal, St. Joseph's, and Orthopedic Hospitals, Orthopedic Surgeon to the Philadelphia General Hospital, Fellow of the American Surgical Association, Member of the Society of Clinical Surgery, Member of the American Orthopedic Association, Fellow of the Philadelphia Academy of Surgery, the Philadelphia College of Physicians, and the American Academy of Medicine. With 630 illustrations, mostly from original dissections, and many in color, by Erwin F. Faber. Philadelphia and London: J. B. Lippincott Company, 1910.

Upon opening this book for the first time the reader feels that he is in the presence of an anatomy *de luxe*, a volume upon which every resource of scholarship and book making has been expended. However dry and uninteresting this subject may have been to him during his student days, a book like this cannot fail to allure him by its elegance of typography and beauty of illustration. The object of the author has been to show the relation of structure to function, whether the latter is normal or disturbed by injury or disease. This emphasis laid upon the practical applications of anatomy tends to redeem it from the disfavor which it has long endured as a dry and uninteresting study. The book is not designed to be a systematic treatise on anatomy; only such anatomical facts are presented as can be shown to be useful in practice. To the student, as a supplement to his regular course in anatomy, and as a preparation for the study of operative surgery, and to the practitioner who would desire to review the subject of anatomy from a vantage point which experience has taught him is the best, this book may be safely recommended. The singular clearness and matchless beauty of the illustrations add greatly to the utility of the book, and on this point the artist is to be commended for his skill.

Forbidden Ground. A novel by Gilbert Watson. New York: John Lane & Company, 1910.

This is a tale portraying sexual emotions. The scene is laid in perhaps the most backward part of Europe, and is certainly one of the most primitive regions of the civilized world, Albainel, and its continuous fierce and wild countries, both as to landscape and inhabitants. The chief interest of the book is centered in its description of monastery life and the intrusion therein of woman. The plot is somewhat incoherent, but on the whole the story is powerful and pleasing, and rises above the level of the ordinary novel of the day.

Die experimentelle Pharmakologie als Grundlage der Arzneibehandlung. Ein Lehrbuch fur Studierende und Aerzte. Von Dr. Hans H. Meyer und Dr. R. Gottlieb, Professoren der Pharmakologie in Wien und Heidelberg. Mit 61 Textillustrationen und 1 farbigen Tafel. Berlin: Urban und Schwarzenberg, 1910.

Both in conception and execution this volume is decidedly original. Starting with the idea that experimental pharmacology, broadly speaking, represents the reaction of living bodies to chemical stimuli, or, what is the same thing, the behavior of living bodies under chemically altered conditions, the authors regard pharmacology simply as one branch of biology. Accordingly, their method of approaching the subject is purely from the biological side, and the old-time grouping of drugs into classes is entirely abandoned. Instead of this the various remedial agents are divided into two large categories, first the etiotropic, which have an action influencing the course of disease, and, second, the organotropic, having an action influencing function. Naturally the former of these is by far the smaller, and comprises the general and specific antiseptics, anthelmintics, and the antitoxins. Most of the book is devoted to the organotropic drugs, and these are treated under headings of function, as digestion, circulation, central nervous system, etc. This, of course, while logical from one point of view, involves difficulties from another. For example, the subject of heart failure during general anesthesia is discussed under the section heading of the general nervous system because ether and chloroform, being anesthetics, are dealt with in this chapter. Furthermore, the same drug keeps appearing in different parts of the book, according to its action on the different functions, and therefore a complete account of the action of any drug is not to be found in any one place, but has to be obtained by hunting it up from chapter to chapter. The very excellent index is of great assistance in this, however, and the objection is not so great as it would appear. From the standpoint of the physician who is seeking to improve his general understanding of the action of drugs and, necessarily also, of pathological physiology, rather than to look up information relative to the treatment of some particular case, this method is admirable, but the book is hardly suitable for students' use. For advanced readers, however, it is fascinating, and the manner of presentation serves to correlate the facts ordinarily so differently arranged. All the most recent work has been incorporated, and fairly full references to the literature are given.

Die Syphilisbehandlung mit dem Erlich-Hata'schen Mittel. Zusammenstellung der bisherigen Erfahrungen. Von Dr. Johannes Bresler, Oberarzt an der Prov.-Heil.—und Pflegeanstalt zu Lüben i. Schl. Zweite, bedeutend vermehrte Auflage. Mit den Bildnissen von Ehrlich und Schaudinn. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1910.

In this pamphlet, of 65 pages, which represents the second edition, the author presents a comprehensive review of what has already been experienced in the use of 606. It is really a résumé of the literature of this subject. As such it cannot fail to be of distinct value to those who are interested in this remedy. The pamphlet is embellished with portraits of Professor Ehrlich and of Schaudinn, the discoverer of the *Spirochæta pallida*.

Manual of Human Embryology. Written by Charles R. Bardeen, Madison, Wis.; Herbert M. Evans, Baltimore, Md.; Walter Felix, Zurich; Otto Grosser, Prague; Franz Keibel, Freiburg i. Br.; Frederic T. Lewis, Boston, Mass.; Warren H. Lewis, Baltimore, Md.; J. Playfair McMurrich, Toronto; Franklin P. Mall, Baltimore, Md.; Charles S. Minot, Boston, Mass.; Felix Pinkus, Berlin; Florence R. Sabin, Baltimore, Md.; George L. Streeter, Ann Arbor, Mich.; Julius Tandler, Vienna; Emil Zuckerkandl, Vienna. Edited by Franz Keibel, Professor in the University at Freiburg i. Br., and Franklin P. Mall, Professor of Anatomy in the Johns Hopkins University, Baltimore, U. S. A. In two volumes. Volume I. With 423 illustrations. Philadelphia and London: J. B. Lippincott Company, 1910.

The simultaneous publication in Germany and America of this manual of human embryology is an interesting evidence that there are no intellectual tariff boundaries between the men of the various nationalities which make up the scientific world. The translation of German works into English is frequent. Occasionally, especially in mathematical and medical subjects, there has been some translation into German of English works, but simultaneous publication in two languages is rare. On the other hand, nine of the fifteen authors are from this country, one from Canada, the rest from Germany and Austria; so that perhaps the presence of a majority of American writers in the text encouraged the American publishers to cooperate with the German. As the title shows, the book is a work on *human* embryology, and it thus occupies a somewhat different place from the great Hertwig "Handbuch," which covers a much larger field. But in the past few years great advances have been made in our knowledge of human embryology, and no one has accomplished more than the German editor of this volume. In the older embryologies a surprising amount of our knowledge was derived, not from a study of human embryos, but from the examination of a series from the lower animals. While undoubtedly many facts so obtained may be employed without much risk to fill up the gaps in our knowledge, yet it has long been considered desirable to obtain a sufficient series of human embryos to draw up conclusions based on such material alone. By arousing the interest of the surgeon a large series of carefully sectioned young embryos has been placed at our disposal, so that now a complete series exists, beginning with the twelfth day after fertilization, thus permitting at last the writing of a text based on human material. The American publishers have wisely increased the size of the page slightly over that of the German edition, thus giving ample room for the insertion of text illustrations and permitting the use of a larger type; but the impression of the type is not quite so clear nor so easily read as in the German volume. On the other hand, the paper is more opaque and less shiny, so that the final difference between the two is very slight. Perhaps the half-tone cuts come out a trifle sharper in the German edition. The book opens well and lies flat, as a laboratory book should, showing good binding, and will no doubt be the standard reference text in the future for all human embryological work.

The work is to be complete in two volumes. In this first volume the introduction and the initial six chapters are by the German editor, Keibel, and are devoted to the germ cells, fertilization, segmentation, young human ova, the formation of germ layers, and the development of the human embryo, and a consideration of its external form. The plates are numerous, and admirably illustrate the text. While we know quite a good deal about the morphology of the germ cells, Chapters 2 and 3, on fertilization and segmentation, together occupy only three pages, and begin respectively with the sentences: "Nothing is known concerning the fertilization of the human ovum" and "The segmentation stages of the human ovum have not yet been observed." It is pointed out, however, that it is not impossible that segmenting ova may be found accidentally at operation if the attention of the surgeon is directed to the importance of the occasional opportunities offered during operation. This means, however, that the surgeon must either be an embryologist or place the perfectly fresh or properly fixed material at the disposal of some one who has the necessary scientific training. The formation of the germ layers also has not been observed in human species, and we must base our opinions concerning this process upon the embryos from the higher mammals. From this point on, however, the gaps are few, and the studies of His, Keibel, and Hochstetter have furnished us with a very complete knowledge of the development of early embryos. Chapter 7, on the development of the egg membranes in the placenta, is by Grosser, and is extremely satisfactory. It is thoroughly well illustrated, well written, and equally well translated, and replaces all other articles on the subject. The studies of Hitschmann and Adler on the endometrium are fully presented, and reproductions of their drawings illustrate the text. In the reviewer's opinion, these monthly changes are not as mathematically periodic as Hitschmann and Adler describe them, and certainly it is possible to find in curetted material places where the various menstrual alterations in the glands and stroma have occurred in typical form, while in other portions from the same uterus the changes are not so extensive. It is certain that these writers have, however, shown that many of the old ideas concerning the endometrium are grossly erroneous, and have given us a firm basis for further study, both on normal tissues and in pathological conditions. The next two chapters are by Mall. That on the Pathology of the Ovum is especially clear and complete, as was to be expected from that writer's monograph on the subject. A fuller discussion of the embryological questions involved in those malformations which do not result in the death of the embryo, but lead to the formation of complicated tumors and cysts, might, however, have very well been added. The author refers to Hertwig's "Handbuch" and Marchand's article on the subject, but if a chapter on pathology is to be included in a book on normal development, such matter might very well have been embodied in this text without expanding it too extensively. Forty pages are devoted to the development of the integument, and almost all the rest of the book is taken up with two admirable chapters on the development of the skeleton and connective tissue, and the development of the muscular system. The last chapter concerns the development of the cœlum cavity and diaphragm and separation of the pericardial pleura and peritoneal cavities. It is possible to offer a few criticisms of the minor points of view in several of the chapters, but on the whole the work is so admirable, so complete, and so satisfactory that any further discussion seems unnecessary.

The Vegetable Proteins. By Thomas B. Osborne, Ph.D., Research Chemist in the Connecticut Agricultural Experiment Station, New Haven, Conn.; Research Associate of the Carnegie Institution of Washington, D. C. London: Longmans, Green & Co., 1909.

The series of monographs on biochemistry, edited by Drs. Plimmer and Hopkins, of which the present volume forms a part, has come to be recognized as one of the most important undertakings yet attempted in this field. It deals with a science that is developing so rapidly that no single textbook can well compass all of it, and still less keep pace with the growth of many of its ramifications, so that the project of issuing from time to time monographs from authoritative hands to cover certain special provinces has everything to commend it. Dr. Osborne is the acknowledged master in the field with which the present volume deals, and his summing up of what is now known concerning the plant proteins is the last word for the time being. The scope of the book is to present a discussion of the general physical and chemical properties of the vegetable proteins, their methods of isolation and classification, etc., rather than to give a detailed account of the individual substances. The relationship between the nitrogenous bodies of animal and of vegetable origin is still a more or less unexplored territory, and it is not unlikely that a more exact knowledge of the vegetable proteins will aid considerably in the understanding of the chemistry of their analogues in animal life. The name of the author is sufficient to convince every worker in the subject of his need of the book—the bibliography appended alone is sufficient to make it invaluable.

The Story of the Bacteria and Their Relations to Health and Disease. By T. Mitchell Prudden, M.D. Second Edition, Revised and Enlarged. Illustrated. New York and London: G. B. Putnam's Sons, The Knickerbocker Press, 1910.

This is scientific material translated into language which is intelligible to the ordinary individual. Of course, much ignorance prevails among the laity as to what bacteria are, their rôle in health and disease, and so forth. A considerable amount of interest is now taken by the public in all questions concerning health and disease, and as the bacteria enter into all these subjects it is well that they should be elucidated by a competent person. That Dr. Prudden has succeeded in making the matter clear is evidenced by the popularity of the first edition of the work.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held January 5, 1911.

The President, Dr. John A. Wyeth, in the Chair.

Address of the Retiring President.—Dr. John A. Wyeth made this address (See page 233.)

Inaugural Address of the President-Elect.—Dr. William M. Polk made this address. (See page 237.)

The scientific session was under the auspices of the Section on Orthopedic Surgery.

The Surgery of the Joints.—Dr. John B. Murphy of Chicago spoke on this subject with special reference to infectious arthritis, its pathology, and treatment. He also considered the new formation of joints and the results obtained. His talk was illustrated with about one hundred and fifty lantern slides. He first spoke of the practical phase of the question under consideration and then the clinical aspects. The anatomy of joints was considered; their structure and formation aided in the pathology (when carefully studied) and directed the line of treatment. The joints were made up of two or more bones, held together by ligaments and a capsule; within the capsule was a synovial lining. The relation of bones to diseases of the joints must be carefully considered, for it had a very important bearing upon the functional results. Among the principal diseases was mentioned acute infective osteomyelitis. This disease rarely attacked the epiphysis. A disease, however, that did attack the epiphysis was tuberculosis, and this disease had no tendency to extend into the shaft of the bone. Joints were made up by bones which were covered by cartilage and a nbrous capsule; this fibrous capsule was an all-important structure so far as the occurrence of infection was concerned. This he illustrated by a wet specimen. Its inelasticity played an important rôle in the deformities which followed lesions of the joints. This capsule had an enormous tensile strength and was feebly vascular, and, therefore, it was almost impossible to infect it. It could readily stand a pressure of from 120 to 140 pounds to the square inch, a point which had a bearing upon pathological processes occurring within it. Being so non-vascular, infecting material could remain within this capsule for a long time before means of escape were offered; this was a very important factor in determining the amount of destruction and the degree of injury in these diseased joints. The fibrous capsule had only a mechanical relation to infection of the joint; it was never the seat of primary infection. The synovial membrane consisted of two layers; one was the endothelial covering, which was smooth, with cells accurately adjusted like shingles, forming a protection; it contained no stomata, a fact which was very important in connection with joint infections. When infection of a joint took place it was through the subendothelial layer of the joints that the microorganisms found entrance. The endothelial layer of the joint was the protective layer. Dr. Murphy called attention to experiments that had been made in Chicago. Virulent pneumococci were injected in dogs with a very fine needle and without producing any trauma or displacement of the endothelial cells; there resulted no response to the infection; when traumatization of the endothelium took place, however, there was a decided response. This showed the protection offered by the endothelial cells against invasion into the subendothelial and other spaces. This had a practical application particularly in the care and management of the surgery of the joints; the greatest respect should be paid to the endothelial cells which covered and protected the underlying vascular and lymph parts. When infection was admitted into a joint without traumatization there was little if any response; if, however, traumatization occurred, fracturing the endothelial cells, then the admitted microorganisms produced an immediate responce. If the endothelial layer was exposed to air it soon became destroyed.

The endothelial layer had a very significant and important bearing on the treatment of joint affections. No serous surface would tolerate exposure to the air without consequent destruction and erosions, etc.; therefore, no joint could be exposed to the air for a considerable length of time without sacrificing that joint. This, in truth, was the key to the management of acute and infective virulent lesions of joints. To make clear what he wished to present he went back and took into consideration the element of trauma in connection with joints, such as fractures, but not dislocations, and the relation played in the limitations of motion. When such an injured joint was held in one position for a long time there was a gradual contraction of the capsule; when held in a fixed position for a long time the capsule also became infiltrated. To make clear his meaning, Dr. Murphy threw many pictures upon the screen. The difficulty encountered in reducing a Colles' fracture was very great; no amount of traction or pulling would accomplish it. He illustrated on the screen his method of treating Colles' fractures. When properly reduced he never saw a case that caused the patient sufficient pain to keep him awake nights. Fractures and injuries of other joints were discussed by him. In closing he emphasized the fact that infectious arthritis should be treated in the same way as an acute appendicitis and the same brilliant results would be obtained. Early operation was demanded or the shaft of the bone would soon be destroyed.

WESTERN SURGICAL ASSOCIATION.

Twentieth Annual Meeting, Held at Chicago, December 19 and 20, 1910.

The President, Dr. John P. Lord of Omaha, in the Chair.

Desmoid Tumors of the Abdominal Wall after Operation.—Dr. E. Wyllys Andrews of Chicago said he had seen only two cases of desmoid tumor in several thousand abdominal operations, both of which followed herniotomies. The rarity of this complication made it worth while to report these two cases. Most of those so far on record were of another type, and followed pregnancy or injury of the fascia above the inguinal region. Keloid was distinct from desmoid in belonging to the skin. Although originating in scar tissue, as after burns or wounds, it always remained movable with the skin, and grew outward, not into the deep fascia. True desmoids were found not in the skin or external cicatrix, nor in the muscles, but in the fascia and aponeurosis, especially of the abdominal wall. Nearly all the reported cases had been in women after repeated childbirth. Histologically, desmoid tumors were pure fibromata of the hard, white form, like fibromata of the other parts, showing coarse whirls of cut fibers macroscopically like uterine myomata and spindle cells microscopically with numerous fibrillæ between. The cells showed oval nuclei. Myomatous and even malignant degenerations might occur, as in similar growths elsewhere, but commonly they were benign. Desmoid tumors should be removed by operation, inasmuch as the tendency was to grow larger and occasionally to start degenerative retrograde or malignant changes. Dr. Andrews then detailed the two cases that had come under his observation.

Dr. J. Clark Stewart of Minneapolis said the point of greatest interest in Dr. Andrews' report was the analogy which he possibly showed between this class of tumors, desmoid tumors, as to etiology with keloid. Keloid arose largely from scar tissue. If they could show that any class of fibroid tumors also arose from the seat of trau-

matism it would be an important point in their etiology and in their analogy to keloid. He doubted whether the term desmoid should be used. Desmoid was an old clinical term which meant just one thing to him, and he thought it should be reserved for that one thing because it had no clear clinical or pathological meaning disassociated from that one clinical condition. Originally desmoids were tumors of the posterior sheath of the rectus muscle, and he must differ with Dr. Andrews that these tumors were found in the majority of cases in the upper part of the abdomen. The majority of the reported tumors he had run across had been found in the lower half of the abdomen, and both pathologically and clinically they had very marked characteristics. Clinically they grew inwardly, so that ultimately they became covered only by peritoneum. They attained considerable size. Quite a number of the reported cases of desmoid tumors were undoubtedly sarcomatous, and it was hard to differentiate a sarcoma under the microscope from the ordinary desmoid, and the after-history of these cases had shown several times they were sarcomas, yet he did not think there was any question about the malignancy of desmoid tumors as originally described.

Dr. A. E. Hertzler of Kansas City, Mo., stated that he thought it was easy to fix the pathogenesis of these desmoid tumors. Any tissue, like the fascia of the external oblique, or any tissue which contained a large amount of the original substance, would, when irritated long enough short of suppuration, give rise to this fibrous tissue hyperplasia. One saw the same tumors subperitoneally about the abdomen. They were histologically very much the same. Histopathologically they differed from fibroma in that they were long, with large oval vacuolated cells, many round cells, and polynuclears. This point was sufficient to differentiate the desmoid tumor from the fibromatous tumor or any tumor analogous to sarcoma.

Dr. Andrews, in closing, stated, as to the identity of keloid with desmoid, that keloid, although it appeared in scar tissue, never involved anything but skin. Keloids were confined to the skin, no matter how great the size they might attain, and were movable and free.

Nonsuppurative Osteomyelitis.—Dr. J. Clark Stewart of Minneapolis stated that three distinct clinical conditions might be classed under this title. First, cases of ordinary osteomyelitis, where, owing to the nonvirulence of the invading germ or to unknown conditions increasing the resistance of the individual, no necrosis was caused. In such cases there was no pus, no sequestrum, but instead in a certain number marked irritative reaction was set up, and there was great overproduction of bony tissue, resulting in a thickened, dense, and painful enlargement of the bone attacked. These cases were quite common, regularly recognized, and properly treated. Second, cases of injury, generally fracture, where a small piece of bone was entirely separated and died, forming about it a closed cavity of dense new bone in which it lay until absorbed, but without suppuration. These cases differed entirely from those of the first class, in that the irritant which caused new production of bone was not bacterial, or at least not primarily so, but a fragment of bone which remained practically aseptic. The third class, and the one to which he especially wished to call attention, differed entirely from both of the above by having no notable beginning, but an insidious onset, although a febrile illness and a slight injury respectively antedated by two years the culmination of the disease by surgical interference. The disease was essentially chronic, but progressive, and regularly misdiagnosed and treated as rheumatism. He had only seen the lesions present in the tibia, but this must be accidental, as it might as well occur elsewhere. The etiology seemed absolutely wanting, as the two cases narrated had nothing in common, while the pathology and symptomatology were identical. This third class seemed to be of a different type of chronic osteomyelitis not recognized by the textbooks on surgery, the nearest approach to a description of them being called "chronic osteoperiostitis," which was certainly a misnomer, for in these cases the periosteum was regularly normal. Their characteristics pathologically were the transformation of the marrow cavity into a multicellular labyrinth filled with a tissue which macroscopically resembled red marrow. There was also synchronous subperiosteal production of bone which resulted in a fusiform enlargement, the new bone being spongy and not dense. Symptomatologically they were characterized by insidious onset, so-called rheumatic pains, worse in damp weather and at night, with slight evening rise of temperature. While the two cases cited each gave a history of an acute causative agent, in neither could this be said to stand in an undoubted etiological position, as the local symptoms in both cases occurred over two years later. What would ultimately happen to a case of this kind without operation could only be surmised. Neither case showed any apparent change during the several months it was under observation, and it seemed probable that the bone would merely remain enlarged and painful until stirred up by a fresh injury or infection, when there would be suppuration and a sinus would be formed. The diagnosis was easy after syphilis was excluded by the non-effect of the iodides. Tuberculous osteomyelitis regularly caused cold abscess and sinus formation, while periosteal sarcoma was generally more rapid and could be eliminated by the use of skiagrams. Fusiform enlargement of a long bone, increasing very slowly in size with point pressure tenderness in various places over the enlarged bone, and slight afternoon temperature, gave a characteristic picture. The treatment was opening the bone and following the morbid process each way until normal bone was reached, cleansing, drying, and filling the cavity with Moorhof's wax, or permitting union by first intention.

Dr. D. S. Fairchild of Des Moines, Ia., stated he had seen a number of cases of this kind which seemed to have arisen from trauma or some injury which had been inflicted on the bone, with involvement of the periosteum to some extent, but the trouble seemed to extend throughout the entire shaft of the bone, the tibia being most commonly affected because it was more subject to traumatic influences. In the cases that had come under his observation the bone had been dense; that was to say, if the condition had existed for a long time the bone became dense throughout its entire extent. In the young cases where the disease had not been progressing for a long time the bone was softer, and when the medullary canal was examined it was found almost entirely occluded by the proliferation of this bony tissue. These cases it seemed to him were more like cases of osteitis in which the inflammation had extended not only into the medullary canal and from the periosteum, but into the bone substance itself, and in the cases of long standing the bone had been very dense, so that, when a gutter was tunneled out, it required a considerable amount of chiseling to do so. While these cases were not very common, yet they were common enough to constitute a matter of very considerable interest to the medical profession.

Dr. W. W. Grant of Denver stated the diagnosis of the pathological condition under consideration was not made early, and that is why they did not see more of these nonsuppurative cases of osteomyelitis. It was his opinion that if they would give them time there would be ultimately death of the part and the formation of pus or of a sequestrum and an involucrum. They saw these cases formerly much oftener than now, because no one thought of operation until there were several sinuses leading to the canal. That was the usual method of dealing with these cases. Today the diagnosis could be made earlier, and if it was oper-

ation should be done earlier, when the patient would be saved several months and years of suffering, and would finally get well with a better leg and a better looking leg. It was necessary to exclude syphilis and tuberculosis, especially in arriving at a proper diagnosis.

Dr. James E. Moore of Minneapolis stated that the principal difficulty in diagnosis was between non-suppurative osteomyelitis and chronic bone abscess. Therapeutic tests would eliminate syphilis. As a rule, syphilitic disease of the bone was bilateral, while non-suppurative osteomyelitis was usually unilateral. Chronic abscess of bone was likely to be limited to one end of the diaphysis, while the condition they were discussing affected the whole diaphysis. The history of these cases was that of a low form of inflammation, with gradual enlargement, the principal symptom being pain, more particularly at night. When they came to operate upon these cases they found the main part of the bone proper was eburnated, and the older surgeons amputated many of these limbs, showing how great the pain was at times. The modern treatment was that pointed out by the essayist.

Dr. Arthur T. Mann of Minneapolis stated that in the last six months he had had two cases of this type of osteomyelitis, in which he had used the Moorhof wax. One patient was a girl, 13 years of age, who had symptoms for two years. She had been kept under observation as a charity patient by another physician who spoke to Dr. Mann about her six months before he saw her. She had the usual symptoms of osteomyelitis of the lower third of the tibia, the pain being worse at night, and the temperature running up to 102° at times, but as a rule it was not as high as that. At the end of two years, when he saw her, she had a fusiform swelling at the junction of the lower with the middle third of the tibia which was very tender. She cried out at night on account of the severe pain. On opening this there was a mass more dense than cancerous tissue, but much thinner than ordinary cortical bone, so that the cortex had thinned out and the medullary cavity had filled in. In the center of this there was pale granulation tissue. This condition lasted two years. This tissue was scooped out and the cavity filled with Moorhof's wax, and the usual closure of the wound made. There was healing by first intention. The pain stopped immediately following the operation. This was a case in which there had never been suppuration.

Dr. William H. Magie of Duluth, Minn., said he would like to speak of a form of treatment which he adopted in a recent case. In this case the bone had been previously troughed by himself. Recurrence took place four or five months later, when Dr. Judd of Rochester, Minn., operated. Later the patient returned to him with all the symptoms reestablished. At the examination he found the tibia for fully eight inches enormously enlarged, so that the case really looked like one of sarcoma. He adopted the plan of not troughing the tibia, but chiseling down at the extreme end of this enlargement, splitting it, removing one-half of the tibia, then applying skin direct upon the raw surface of the bone that he had left, after removing half of the diameter of the tibia fully eight inches in length. The wound healed perfectly by first intention, and the pain was relieved immediately. The patient had been well since and working at his occupation in the woods as foreman of a lumber crew of loggers.

Dr. A. E. Hertzler of Kansas City, Mo., said that in arriving at the pathogenesis of this condition he did not think they would make a mistake if they called it a desmoid tumor of the bone. If the tumor in Dr. Andrews' case had occurred in the medullary cavity the patient would have had this trouble they were discussing. In the chronic sclerosing type of bone disease they had a milder form of infection which produced an exudate which was capable of being organized, and not as in the more acute types which form an exudate which was not all organized. These conditions could be rather clearly followed out if one took the trouble of applying tinctorial chemistry to these various tissues. Rather unconsciously, he suspected, in the use of Moorhof's bone plug they were imitating in a measure a very mild type of infection. The iodoform produced an exudate which was capable of being thrown down into a fibrillar type of fibrin, and it was by active hyperemia acting on the substance which produced an exudate, after forming this type of fibrin, that healing was brought about.

Dr. M. L. Harris of Chicago stated that in the cases belonging to the subgroup which had been described by the essayist there was no material enlargement of the bone. There was no condensation of the bony cortex. The disease usually affected the shaft of the bone. In the interior of the bone they found the red marrow which Dr. Stewart mentioned; it was very soft, almost semiliquid in some cases. These cases were characterized by extreme pain. The most interesting and typical case of that kind he saw was a man who had been treated for syphilis. He had visited several watering places in Europe, but returned to this country without being relieved. His pain was so severe that he was obliged to take morphine to afford relief. There was extreme pain in the shaft of the humerus. These cases were sensitive when the bone was percussed by hammer or when deep pressure was made. All that was necessary to do in such cases was to open the medullary cavity, remove a portion of the cortex, relieve tension, and these cases recovered.

Primary Sarcoma of the Appendix.—Dr. Everett O. Jones of Seattle, Wash., said that primary sarcoma of the appendix was an extremely rare condition. He detailed a case on which he had operated successfully, and then drew the following conclusions: 1. An accurate diagnosis before operation appeared to be impossible. In every case the symptoms were those of some type of appendicitis. 2. Pathologically the round-cell sarcoma predominated, next to this the spindle-cell type. 3. Inflammatory changes either chronic or acute very frequently accompanied the growth. 4. The immediate prognosis and prospect of freedom from recurrence were very good. 5. The fact that primary sarcoma of the appendix that took its origin in an inflammatory process occurred formed a very strong additional argument for the removal of all appendices which showed evidences of inflammation.

Dr. A. E. Hertzler stated that he had no hesitation in referring to this case as one of desmoid of the appendix, because he did not know what a desmoid was, and he did not know the nature of the appendix the essayist removed in this particular case. It was common to have microscopic pictures in these chronic gut inflammations which looked very much like sarcoma; hence the greatest care possible was necessary to make the differentiation.

Dr. S. C. Beede of David City, Neb., said before hearing Dr. Hertzler's remarks he was under the impression that primary sarcoma of the appendix was a surgical curiosity, but now he was not sure that it was even a curiosity. Ever since Warren reported his case in 1898 there had been considerable investigation carried on with a view to finding malignant disease of the appendix. In the department of pathology of St. Mary's Hospital, Rochester, Minn., of 5,000 appendices removed for disease, there were only 22 cases of carcinoma of the appendix, and not a singl case of primary sarcoma of the appendix developed.

Dr. William C. McCarthy of Rochester, Minn., stated that he had had the privilege of examining about 5,000 appendices which were removed in Rochester, and since that investigation was made he had extended the list to about 10,000, and in all this series he had not seen one

of sarcoma of the appendix. In the first 5,000 cases examined, as Dr. Beede had just stated, there were 22 cases of carcinoma of the appendix. Two of these he had previously diagnosed as endothelioma, which showed that the differential diagnosis between endothelioma and sarcoma was a difficult one. These were all very early cases, and in only one out of 17 was the serosa involved.

Dr. Donald Macrae of Council Bluffs, Ia., stated he had had eight or ten cases which from macroscopic appearances and the sensation imparted to his fingers appeared to be sarcoma of the appendix, yet he agreed with Dr. Hertzler. Unfortunately, in the cases he had had the disease was not entirely confined to the appendix, but involved the cecum, and there were adhesions which tore away like frozen meat, and the mass had a sarcomatous feel.

Dr. Arnold Schwyzer of St. Paul, Minn., stated that a few years ago, while on a visit to Switzerland, a patient presented himself with a large tumor of the diaphysis of the femur. Professor Kocher was to operate on this patient, believing the tumor was malignant. Sections were taken from it and examined by Professor Langhans. These sections had to be frozen, as a quick report was necessary. Professor Langhans made the positive report that the tumor was a round-cell sarcoma. In the meantime, while waiting for the report, Kocher observed the tumor and found some grayish little dots here and there which appeared to him to be deteriorated tissue, and came to the conclusion that it was a case of infectious granuloma. He acted accordingly, left the femur and saved the patient's leg. No recurrence took place. It was difficult to make a differentiation between infectious granuloma and sarcoma.

Dr. Emerson F. Root of Salt Lake City stated that about six or seven years ago he had a case of what he thought was primary sarcoma of the appendix. The patient had had a chronic appendicitis for more than a year. He refused operation, and at this time, for a month or two, he was rapidly running down and asked to be operated on. Operation was performed. The appendix was found to be very large, five or six inches long, and an inch or more in diameter, with its lumen almost occluded. It was rather hard and very loosely attached. The cecum was not involved to any great extent. The appendix was removed, together with a small portion of the head of the cecum. The wound healed by primary intention. Two or three months later the patient died. In this case the microscopic diagnosis was made of round-cell sarcoma of the appendix.

Dr. William Jepson of Sioux City, Ia., stated that he was adverse to coining new terms that did not express anything. The term desmoid tumor arose from the fact that prior to their histological conception of what these tumors were like they were classed as having developed from hard band-like masses found in the rectus muscle or else in the transverse fascia. The term desmoid meant hard band, and these hard bands were found in the abdominal wall, and it was found tumors developed from them, and consequently they were called desmoids. Was there any reason why they, as surgeons, should adhere to such a term when these tumors were strictly fibromata That was all they were.

Dr. Jones, in closing, said he regretted he did not bring the sections along with him. He would say, however, that these sections were submitted to four or five pathologists in his neighborhood and all of them pronounced the disease sarcoma.

Acute Suppurative Appendicitis.—Dr. Willard Bartlett of St. Louis described the operative technique in this condition at which he had arrived after years of simplification. 1. The abdomen was invariably opened through a gridiron incision immediately over the dull area if one could be made out, otherwise at McBurney's point. It was very rarely the case that this incision had to be enlarged, which could be done, though, with slightly greater difficulty than was the case in ordinary through and through openings. His experience had taught him that it was just as applicable to pus work as to any other. 2. Immediate search for the appendix was made, it being his practice always to remove it if it could be found without unnecessary loss of time or disturbance of many adhesions in the presence of a large amount of pus. He did not often go so far as to turn out the head of the cecum in order to find the appendix, but considered this advisable where this carried with it the adherent viscera which completely surrounded a collection of pus, to be opened outside of the abdomen at the removal of the appendix. It was rarely his custom to do much or any so-called walling off with gauze in the search for the appendix. They long ago learned that intraabdominal tension forces liberated pus toward the opening in the wall rather than in any other direction. On the other hand, undoubted harm was done by gauze packs. At the same time ready access to the viscera was interfered with. While in clean work he made a peritoneal autoplasty when working on the appendix or any other viscus covered by peritoneum, in these pus cases he simply tied a strand of catgut around the base of it, including the mesenteriolum, and cut it off. Not only did this save time, but the appendix and adjacent cecum were often so indurated and friable that ordinary Lembert stitches would not hold. By way of justifying a search for the appendix in the acute stage, it was hardly necessary to state that a variety of dangerous complications were avoided by its removal. In a very small per cent. of these cases a fecal fistula had made its appearance, but not one had failed to close spontaneously in a few days. 3. Drainage was instituted in every case where exudate was met with. This was most readily and accurately accomplished, to his thinking, by tying at its middle a strip of rubber dam or a ribbon cut from an old rubber glove in the catgut ligature on the base of the appendix mentioned above. This treatment sufficed for ordinary cases, although he was not here dealing with remote pus collections, which were infrequent early in the disease and which must be considered as complications not to be dealt with in any simple routine procedure. Drainage was further aided by placing the patient in bed on the face directly after the operation. In a few days the catgut ligature was absorbed and the drain came out of its own accord. 4. Suture of the deeper layers of the abdominal wall was never attempted unless the muscle-splitting incision had been considerably enlarged. The drain practically filled the small dead space, resulting from the spontaneous closure of such incisions, thus re-establishing intraabdominal pressure sufficiently for their purpose. In the middle of the skin wound was placed one or two clips at each side of which one-half of the rubber drain emerged, its two ends being fastened together by a clip which prevented the possibility of its being drawn into the abdomen. Thus one had practically coapted the edges of an infected wound without any danger of pus retention in the depths or under the skin. After the two drains had been removed, at the end of a week, the resulting defects in the skin were closed with adhesive plaster, and in two weeks after the operation most of these patients were out of bed with a solid abdominal wall and with the skin wound completely healed or almost so.

Surgery of the Mediastinum.—Dr. B. Merrill Ricketts of Cincinnati spoke of the progress that had been made in the surgery of this region. The conditions now operated on in this region included abscess, dermoids, lipoma, foreign bodies, hemorrhage, enchondroma, hydatids, etc. Strange as it might seem, the two conditions

that had been operated on most frequently were abscess and dermoids. In the last ten years numerous devices had been introduced for positive and negative pressure. There had been nothing done with the Sauerbruch apparatus that could not be done without it, so that there were no special advantages attending its use. In his experience he had found that he could expose the tissues of the esophagus, a bronchus, or any portion of the lung, pericardium, or any portion of the mediastinal space without this apparatus. But surgeons now had something at their command which was of special interest and usefulness, namely, the Matas method of inflation. With this means the chest could now be opened and anything done upon the tissues within it by the method that had been suggested.

A New Principle in the Action of Antiseptics.—Drs. M. G. Seelig and C. W. Gould of St. Louis said that they had developed the idea that effectiveness in the action of a germicide was predicated upon two factors: 1. The inherent power of destroying germ life, and, second, the power of penetrating tissues, blood clot or exudate, in order to reach the bacteria. The fact was emphasized that, as a rule, surgically considered, bacteria were not found free on the body surface, but in the depths, and the problem of reaching them was similar to the problem confronting naval ordnance experts, namely, the creation of sufficient driving force to enable a projector (germicide) to reach the vitals of a warship (protoplasm of a bacterium.) This power of penetration merely expressed the physical and physiological phenomena known as osmosis. They summarized the methods used in the past for testing the efficiency of germicides, and showed that they were all untrustworthy from a surgical point of view, in that the laboratory conditions were not made to conform with those of actual experience. The powers of a germicide had not been thoroughly or correctly tested unless its osmotic properties had been taken into consideration. Their method consisted in subjecting various organisms—typhoid, colon, streptococcus, staphylococcus—to the action of various germicidal solutions. The organisms were used in simple broth cultures and they were invariably separated from the germicide by either a specially constructed celloidin membrane, or by a live animal membrane skin, mesentery, omentum, diaphragm. The results of the experiments might be summarized as follows: 1. Germicidal drugs such as bichloride, carbolic, cresylic acid and lysol, in watery solution of various strengths, had no apparent effect on organisms that were separated from the germicide by a thin layer of celloidin, an excellent osmotic membrane. Iodin in watery solution was an exception. It osmosed through the celloidin and destroyed the organisms. 2. With animal membranes, excepting a three per cent. watery solution of carbolic acid, the same results were secured as with celloidin membranes. 3. Alcohol, above sixty per cent. strength, penetrated the celloidin membranes with a degree of rapidity and effectiveness proportionate to its percentage strength. Ninety-five per cent. alcohol killed the organisms in from three to ten minutes; eighty per cent. in about an hour and a half; seventy per cent. in about seven hours, whereas fifty per cent. did not kill in twenty-four hours. Ninety-eight per cent. was not perceptibly more efficacious than ninety-five per cent. 4. The addition of bichloride or carbolic acid did not increase the osmotic power or intensify the germicidal action of alcohol. 5. The addition of iodin to the alcohol made a solution of heightened osmotic power and increased the germicidal power. 6. The fatty constituents of the tissues, the skin, for example, rendered them better osmotic membranes for alcohol and tincture of iodin, for the reason that alcohol was soluble in these fats. This phenomenon underlay the fact that thorough washing of the skin interfered somewhat with the germicidal effect of the subsequent application of alcohol. The generally accepted explanation that washing the skin was a disadvantage because it softened and swelled the epidermis was incorrect.

Definite Knowledge Obtained by Means of the X-Ray.—Dr. E. M. Sala of Rock Island, Illinois, reported twenty-two cases illustrating a variety of conditions in which the *x*-ray proved very useful and decidedly advantageous. His conclusions were: The *x*-ray, when in good working order, was one of the most valuable adjuncts to good surgical work they had at their command. It helped to make surgery a more exact science; it gave them a much clearer understanding of their cases and would eventually lessen to a great extent the vast number of cripples that were unavoidable previous to the time of its use.

Dr. Daniel N. Eisendrath of Chicago showed a specimen which was obtained at autopsy of the bladder, ureter and the left kidney with dilated pelvis. In dissecting the specimen several phleboliths were found. These phleboliths lay close to the ureter, entering into the posterior wall of the bladder. He exhibited an *x*-ray plate showing the progress that had been made in the *x*-ray diagnosis of ureteral calculi. He emphasized the great value of the *x*-ray as an aid not only in fractures, but in many other fields of surgery.

Dr. Willard Bartlett of St. Louis said, in regard to wiring fractures which was touched on in the paper, given cases in which an open operation was decided upon, he wanted to speak emphatically in regard to the usefulness of the Lane plate. Since having observed Mr. Lane's work in London, about six months ago, he had had occasion to screw on steel plates in from forty to fifty cases, and with the exception of fracture of the patella, of which he had had only one in this series, and with the further exception of fracture near the ends of the long bones, he believed that wire had been driven out of business by the Lane plate.

Dr. A. H. Levings of Milwaukee wished to say a few words with reference to the treatment of fractures. He had listened with a good deal of interest to what Dr. Bartlett had said about having put on Lane plates in forty or fifty cases of fractures since he had returned from London six months ago. He had had the pleasure of meeting Mr. Lane in Milwaukee a few weeks ago, while on a visit to this country, and discussed with him the question of the universal use of these plates, and he would like to ask Dr. Bartlett whether he did not find it difficult to get patients who would allow him to operate on every case of fracture. He thought any man who had used the Lane plates on forty cases within six months must have operated on every case that had come under his observation. Where fixation was required to immobilize bone fragments that could not be otherwise immobilized the Lane plates were infinitely better than wire, because most of the members who had examined skiagrams of fractures after they had been wired, especially of the femur, had found in many instances that the wires failed to hold the fragments in approximation, and in some instances the deformity and the displacements of the fragments had been greater after wiring the fragments than before. In regard to spiral fractures of the tibia, they were quite common. For some four or five years he had been treating all these fractures of the lower extremity without wiring, without any mechanical fixation whatever, and he had yet to find a fracture that could not be reduced and held in good approximation without the use of either Lane's plates or wire. With the collaboration of Dr. Mueller, of Chicago, some five years ago, he devised an apparatus for the mechanical extension of the leg while a plaster cast for the purpose of immobilization was being put on the leg, and with it he had obtained excellent results.

Dr. Emerson F. Root of Salt Lake City stated that if you went before a court of justice every juror, every person in the court room, had an idea of the *x*-ray picture, and he read it to suit himself, and this was not at all in accordance with the idea of the man who took the picture. No man was so wise that he could offhand read every *x*-ray plate or very many *x*-ray plates without gradually educating himself to do so, and in going before a court he thought the person who had the *x*-ray plates to explain should insist on having his version of the matter taken by the jury and by the court.

Dr. Sala, in closing, stated that he was a firm believer in the use of the Lane plates, but they would not be a good substitute for the wire in the class of cases he had mentioned.

(To be continued.)

Philadelphia County Medical Society.

At a stated meeting held Dec. 28, a symposium on "Pneumonia" was held. Dr. W. M. Late Coplin discussed "Pathology and Morbid Anatomy," Dr. James M. Anders "Symptoms and Complications," Dr. Augustus A. Eshner "Differential Diagnosis," Dr. Charles F. Nassau "Surgical Complications and Their Treatment," Dr. Arthur Newlin "Medical Treatment." Dr. Coplin questioned the specificity of the diplococcus of Weichselbaum, pointing out that croupous pneumonia may be due to other microorganisms. He discussed at some length also the portal of entry of the infecting microorganism, inclining to the view that the air passages constitute the usual channel of entrance. He held that the three stages into which the disease has been divided really represent a single process in continuity. By means of lantern slides he illustrated the histological lesions in the alveoli taking place in the course of the disease. Dr. Anders made a full statement of the symptomatology and he recited the most common complications. Dr. Eshner stated that pneumonia is to be differentiated from disorders with which it presents one or more symptoms or physical signs in common. Among these are acute pleurisy, with or without effusion, pulmonary tuberculosis, congestion of the lungs, pulmonary edema, infarction, abscess, gangrene, bronchiectasis, syphilis, actinomycosis, malignant disease of the lung, pericardial effusion, and typhid fever. Dr. Nassau detailed quite a long list of surgical complications, including serous pleural effusion, empyema, gangrene and abscess of the lung, pericardial effusion, disease of bones, and appendicitis. Dr. Newlin pointed out that there is no specific treatment. Therapeutic indications must be met as they arise. Especially must the circulation be sustained and toxemia opposed. Dr. Henry D. Jump discussed the value of a study of the blood-pressure as a factor in the prognosis and treatment of pneumonia. He pointed out that when the pulse rose in frequency to the level of the blood-pressure expressed in millimeters of mercury the indication was presented for sustaining the circulation by appropriate measures. Dr. J. Norman Henry reported successful results from the hypodermic injection of seven and a half grains of quinine three or four times a day.

Abnormal Cases of Diphtheria.—R. García Rijo, after describing 15 cases of abnormal diphtheria, gives the following conclusions: 1. The malignancy of the disease is not always directly related to the production of pseudomembranes. 2. The serum may fail if applied late. 3. A severe toxemia may occur in the first three days. 4. Many cases of apparently benign inflammation of the throat react favorably after serum injection. 5. The serum is so harmless that it should be applied freely as a preventive even in the newly born. 6. The preventive application of serum allows a mother to nurse a diphtheritic child at the same time as a healthy one previously immunized.—*Crónica Médico-Quirúrgica de la Habana.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

June, 1910.

ANATOMY.

1. Give a general classification of bones and name a bone in each class.
2. Name structures transmitted through any four of these six foramina: Foramen magnum, jugular foramen, sphenoidal fissure, foramen ovale, foramen rotundum, optic foramen.
3. What bones enter into formation of the nasal fossæ?
4. Name cavities of the heart and describe the valves.
5. Locate the imaginary lines dividing the abdominal cavity into regions. Name regions and state contents of lower central region.
6. Describe the lacrymal apparatus.
7. Through what arteries is the collateral circulation carried on after ligation of subclavian artery (lower third)?
8. Locate and describe Peyer's patches.
9. What nerves supply the tongue?
10. Give origin, insertion, action and nerve supply of the latissimus dorsi and biceps femoris muscles.

PHYSIOLOGY.

1. (*a*) What is meant by muscular contraction? (*b*) What effect has the temperature or veratrin upon muscular contraction? (*c*) What is the difference between simple and compound or tetanic contraction, and what are the chemical changes in the muscle during contraction and rigor?
2. (*a*) State briefly the general physiology of the nerve cell and what is meant by the neuron doctrine.
3. What is meant by the knee jerk? (*b*) What use are the knee jerk and spinal reflexes as diagnostic signs?
4. What changes take place during sleep, and what are the neuron and anemia theories of sleep?
5. Give the composition of the blood, its reaction, specific gravity, temperature, difference between arterial and venous, the amount in the body, and the time required for a complete circulation.
6. (*a*) What is meant by blood pressure, and how determined? (*b*) What effect has menstruation upon blood pressure? (*c*) What effect has the blood pressure in the arteries upon the pulse rate?
7. (*a*) Give the difference in each ingredient between inspired and expired air. (*b*) The effect of work upon the respiratory movement. (*c*) The cause of the first respiratory movement.
8. (*a*) Give composition and specific gravity of the saliva and the gastric juice, and the composition and physiological action of the pancreatic secretion. (*b*) Which is the only secretion in the body containing a free acid, and what is the acid?
9. State the general physiological importance of bile, and what would be the effect of complete occlusion of the bile duct?
10. (*a*) Name the nerves of submaxillary gland, and state in full the effect of stimulating each. (*b*) What is meant by the paralytic "secretion?"

CHEMISTRY.

1. Define (*a*) chemistry, (*b*) chemical compound, (*c*) chemical affinity, and (*d*) chemical reagents.
2. What does the presence of an abnormal quantity of chlorine in drinking water indicate, and give tests to determine its presence.
3. State the names and the general chemical and physical properties of the "halogens."
4. State of the two chlorides of mercury (*a*) their names, (*b*) chemical formulas, (*c*) composition, (*d*) solubility, (*e*) color and other properties.
5. What are normal and decinormal solutions, and how are they made?
6. Complete the following equations:

$$FeSO_4 + K_2CO_3 =$$
$$NH_4Cl + KNO_3 =$$
$$PCl_3 + 3H_2O =$$
$$Zn_2 + 2HCl =$$
$$NH_3 + HCl =$$

7. (*a*) State the specific gravity of normal urine, (*b*) causes of deviations in the specific gravity of urine, and (*c*) what is the reaction of urine during the formation of phosphatic calculus?
8. Give a chemical test for each of the following: (*a*)

Proteids, (*b*) phenol, (*c*) lactic acid, (*d*) amylum, (*e*) creosote.

9. State of silver nitrate its composition, properties, and names by which it is known.

10. (*a*) Give tests and antidotes for nitric acid. (*b*) What are amalgams? (*c*) What are "indicators"? (*d*) Give a brief outline of the differences between "leucomaines" and "ptomaines." (*e*) What kinds of blood are distinguished, and give the differences between them.

MATERIA MEDICA.

1. What are alkaloids? What is an infusion? What is a decoction? Define fixed and volatile or essential oils.

2. Give two remedies of the following classes and the doses of each: Galactagogues, sialagogues, emetics, antiseptics, anthelmintics, diuretics, antipyretics.

3. Give six official preparations of iron used internally and give dose of each.

4. Cinchona—mention the most important preparations and their doses.

5. Arsenic—mention the official preparations and average dose of each. Give the official antidote for arsenical poisoning and how prepared.

6. Name five official acids used internally, and give dose of each.

7. Name three preparations obtained from the animal kingdom, and give source of each.

8. Give six official preparations of mercury used internally and dose of each.

9. Name five official powders, composition, and dose of each.

10. Write me a prescription, using official terms, containing compound tincture of gentian, tincture of nux vomica, and bicarbonate of soda. Write one containing reduced iron, arsenious acid, sulphate of strychnine, and sulphate of quinine. One containing digitalis, nitrate of potassium, and extract of buchu. One containing pepsin, subnitrate of bismuth, and paregoric.

THERAPEUTICS.

1. Name five antispasmodics and the general indications for their use.

2. Write two prescriptions in Latin, each containing four ingredients, one in dry, the other in liquid form, with directions for administration, and state the conditions for which they are to be used.

3. What is an antitoxic serum? Name disease most amenable to serum therapy. Give source of serum and describe method of administration.

4. What are the therapeutic uses of opium? Strychnia? Describe symptoms of poisoning by each.

5. Give the indications for venesection and describe the operation.

6. Give the physiological action and therapeutic uses of colchicum.

7. Give the physiological action, therapeutic use, and effect of overdose and constant use of digitalis.

8. Describe purpose and method of introduction of vaccine lymph into human system and physiological manifestations.

9. Give mode of action of cardiac sedatives, cardiac stimulants, cardiac tonics. Name three of each.

10. What is meant by the terms "antagonists," "antidotes"? Describe uses and modes of action.

PATHOLOGY.

1. State the method you would use in preparing a specimen of fresh kidney tissue for microscopical examination.

2. State the general principles of the methods used in isolating and identifying bacteria.

3. How would you prepare a specimen of sputum in order to demonstrate the presence or absence of tubercle bacilli?

4. Give the life history of the trichina spiralis and the pathology of a case of human trichinosis.

5. If you were given two specimens of serum and told that one was human and the other bovine, how would you proceed to differentiate them?

Or, what is anaphylaxis, and what alarming symptoms are sometimes due to this phenomenon?

(Answer either one of the above, but not both.)

6. What would you expect to be the macroscopic appearances of the abdominal viscera in a case of typhoid fever dying of hemorrhage in the third week of the disease?

7. State in the order in which they occur the changes which lead from the healthy lung tissue to a healed tuberculous cavity.

8. What changes, not local, may be noted during the course of, and what sequela may follow, an attack of diphtheria? What is the best way to prevent these changes, and why?

9. What is arteriosclerosis? What are the common causes leading to this condition? Mention its effect on the heart and kidneys.

10. What changes in the brain may lead to, occur in, and follow a stroke of apoplexy the effect of which is paralysis of the right side?

PRACTICE.

1. Define (*a*) Enteroptosis, (*b*) Ludwig's angina, (*c*) purpura, (*d*) myxedema, (*e*) angina pectoris.

2. Define (*a*) Rabies, (*b*) ascaris lumbricoides, (*c*) empyema, (*d*) cholelithiasis, (*e*) dysphagia, and give some of the causes.

3. Give differential diagnosis between measles and scarlet fever.

4. Give differential diagnosis between serofibrinous pleurisy and pneumonia.

5. Give differential diagnosis between hysteria and epilepsy.

6. Give treatment of a case of typhoid fever and the most frequent complications.

7. Give treatment of early pulmonary tuberculosis, and state in detail what methods should be employed to prevent contagion from such a case.

8. Name types of chronic nephritis and symptoms of each type.

9. What diseases are likely to occur in the right inguinal region?

10. Give symptoms and treatment of gastric ulcer.

OBSTETRICS.

1. Give general directions and preparation of the patient for labor and delivery.

2. What anesthetic should be used in labor and the indications for use of each?

3. What conditions demand the emptying of the uterus prior to quickening, and what is the technique of the procedure?

4. What indications require the use of forceps? Give the method of using them, and the dangers of their use to mother and child.

5. What is the mechanism of labor in a breech presentation?

6. Describe Credé's method of expressing the placenta

7. What are the common causes of hemorrhage during and after labor?

8. Give indications for and method of amputation of the cervix uteri.

9. Give causes and treatment of pelvic peritonitis.

10. What are the dangers to be avoided in performing a dilatation of the cervix and curetting of the uterus?

SURGERY.

1. What are the signs of intestinal perforation in typhoid fever and what is the surgical treatment?

2. Describe what is generally known as the radical operation for the cure of cancer of the breast.

3. Describe intubation of the larynx, laryngotomy, and laryngotracheotomy. Give indications for each.

4. Give symptoms and treatment of acute catarrhal conjunctivitis.

5. Describe phimosis, paraphimosis, hypospadias, epispadias.

6. Describe two operations for cancer of the stomach.

7. Define the following operations: (*a*) Enterotomy, (*b*) enterostomy, (*c*) enteroanastomosis, (*d*) enterectomy.

8. Define and describe the following diseases of the hip: (*a*) Coxitis, (*b*) coxitis tuberculosa, (*c*) coxa vara.

9. Describe exstrophy of the bladder, cause, treatment: (*a*) palliative, (*b*) operative.

10. Describe mastoiditis, acute and chronic, causes and treatment of each.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

June, 1910.

ANATOMY.

1. *Bones are classified* as: (1) Long (as femur); (2) Short (as scaphoid); (3) Flat (as parietal); and (4) Irregular (as sphenoid).

2. *Foramen magnum* transmits: Medulla and membranes, vertebral arteries, spinal accessory nerves, anterior and posterior spinal arteries, and occipito-axial ligaments.

Jugular foramen transmits: Lateral and inferior petrosal sinuses, branches from occipital and ascending pharyngeal

arteries, and glossopharyngeal, pneumogastric, and spinal accessory nerves. *Sphenoidal fissure* transmits: Third, fourth, sixth, and first division of the fifth cranial nerves, branches of the middle meningeal and lacrymal arteries, the ophthalmic vein, and filaments of the sympathetic nerve. *Foramen ovale* transmits: Third division of fifth cranial nerve, small meningeal artery, and small petrosal nerve. *Foramen rotundum* transmits: Second division of fifth cranial nerve. *Optic foramen* transmits: Optic nerve and ophthalmic artery.

3. Nine bones enter into the formation of each nasal fossa: Sphenoid, ethmoid, frontal, vomer, nasal, superior maxillary, lacrymal, palate, and inferior turbinated.

4. See Cunningham's "Anatomy" (1909), page 786; or Gray's "Anatomy" (1908), page 567.

5. See Cunningham's "Anatomy" (1909), page 1047; or Gray's "Anatomy" (1908), page 1243. The lower central (hypogastric) region contains: Small intestine, and sometimes bladder, uterus, cecum, and vermiform appendix.

6. See Cunningham's "Anatomy" (1909), page 740; or Gray's "Anatomy" (1908), page 1151.

7. The collateral circulation after ligation of the third part of the subclavian artery is: "Suprascapular and posterior scapular above, with acromiothoracic infrascapular, subscapular, and dorsalis scapulæ below; internal mammary, superior intercostals, aortic intercostals above, with long thoracic and scapular arteries below; plexiform vessels from branches of subclavian above, with branches of axillary below."—(Bickham's *Operative Surgery.*)

8. See Cunningham's "Anatomy" (1909), page 1064; or Gray's "Anatomy" (1908), page 1304.

9. The *nerves which supply the tongue* are: (1) The lingual branch of the inferior maxillary division of the trigeminus (sensation); (2) chorda tympani (taste); (3) lingual branch of the glossopharyngeal (taste and sensation); (4) hypoglossal (motor).

10. Latissimus dorsi. *Origin:* Six lower dorsal vertebræ, lumbar fascia, crest of ilium, and last three or four ribs. *Insertion:* Bicipital groove of humerus. *Action:* Depresses, draws back, adducts, and rotates the humerus inward. *Nerve supply:* Long subscapular.

Biceps femoris. *Origin:* Tuberosity of ischium, great sacrosciatic ligament, and linea aspera. *Insertion:* Outer side of head of fibula. *Action:* Flexes leg on thigh and rotates leg slightly outward. *Nerve supply:* Great sciatic.

PHYSIOLOGY.

1. (*a*) By muscular contraction is meant the property which a muscle has of shortening, under appropriate stimulation. (*b*) Temperature. *Cold* first increases contraction, then lessens it; later on the latent period, the period of contraction, and period of relaxation are all lengthened, particularly the last period. *Warmth* increases contraction at first and shortens all the periods; above about 40° C. heat rigor supervenes. Veratrine shortens the latent period and lengthens the contraction and relaxation periods. (*c*) A *simple contraction* results when a muscle nerve preparation is stimulated by a single induction shock, when a single contraction of the muscle occurs. But when a series of stimuli is applied so rapidly that the effects of the former stimuli have not passed off before the later ones reach the muscle the muscle is at no time completely relaxed, and *tetanic contractions* are produced. *Chemical changes in muscle during contraction:* Oxygen is used up; carbon dioxide, sarcolactic acid, extractives, and some organic salts are formed; glycogen is changed into glucose. *During rigor mortis:* Carbon dioxide is given off, sarcolactic acid is formed, acid phosphates are formed.

2. See Cunningham's "Anatomy" (1909), pages 445 and 448; or Gray's "Anatomy" (1908), pages 820 and 822.

3. The *knee jerk* is a tendon reflex, and consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendons; afferent or sensory nerve; posterior roots and anterior horn of the spinal cord; the efferent or motor nerve; and the muscle itself. As diagnostic signs these reflexes show the integrity of the reflex arc, and by a careful study of the same we are enabled to locate lesions of the cord or nerves.

4. During sleep the metabolic processes are lowered, the brain is anemic, consciousness is suspended, reflexes and nerve excitability are diminished, cerebral activity is almost suspended, the eyes are closed, the pupils are contracted, respirations are slower and deeper, the pulse is slowed, most secretions are diminished. *Neuron theory of sleep* is that sleep is caused by the retraction of the arborization of the nerve fibers from the cells of the cortex. The *anemia theory* makes it due to the lessened blood supply to the brain.

5. Blood is *composed* of plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and inorganic salts). The *white corpuscles* consist of water and solids (proteids, nuclein, lecithin, histon, etc.). The *reaction* is alkaline: *Specific gravity,* about 1055 to 1062. *Arterial* blood is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer. *Venous blood* is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein). The *total quantity* of blood is supposed to be about one-thirteenth of the weight of the body. The *time required* for a complete circulation of the blood through the body is about twenty-three seconds.

6. (*a*) *Blood pressure* is the pressure of the blood due to the ventricular systole, the elasticity of the walls of the arteries, and the resistance of the capillaries. It is determined by means of instruments called Sphygmomanometers. (*b*) The blood pressure falls at the time of the menstrual periods. (*c*) The blood pressure increases as the pulse rate decreases, and *vice versa;* the two conditions seem to be in inverse ratio.

7. (*a*)

	INSPIRED AIR.	EXPIRED AIR.
Oxygen	21 per cent.	16.6 per cent.
Nitrogen	79 per cent.	79 per cent.
Carbon dioxide	0.04 per cent.	4.4 per cent.
Other gases	Rare.	Often present.
Watery vapor	Variable.	Saturated.
Temperature	Variable.	That of body.
Volume	Varies.	Diminished.
Bacteria	Always present.	None.
Dust	Always present.	None.

(*b*) Work, if violent, may cause the extraordinary muscles of inspiration to be called into play. (*c*) The first respiratory movement is due to the stimulation of the respiratory center in the medulla by the increased carbon dioxide in the blood consequent on the tying of the cord and thus depriving the infant of oxygen from the mother.

8. (*a*) *Saliva* consists of water and solids (mucin, ptyalin, a protein, potassium thiocyanate, sodium chloride, sodium carbonate, calcium phosphate, calcium carbonate, magnesium phosphate, potassium chloride); its specific gravity is about 1002 to 1005. *Gastric juice* is composed of water and solids (pepsin, hydrochloric acid, chlorides of sodium, potassium, calcium and ammonium, and phosphates of calcium and magnesium); its specific gravity is about 1003 to 1006. *Pancreatic secretion* consists of water and solids (trypsin, amylopsin, steapsin, a milk-curdling enzyme, protein, leucin, tyrosin, xanthin, soaps, potassium and sodium chlorides, and phosphates of sodium, calcium, and magnesium).

The *trypsin* changes proteids into proteoses and peptones, and afterwards decomposes them into leucin and tyrosin; the *amylopsin* converts starch into maltose; the *steapsin* emulsifies and saponifies fats; and the milk-curdling ferment. All of these act in an alkaline medium only.

9. *The functions of the bile* are: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action. When the bile duct is completely occluded the bile is reabsorbed by the lymphatics of the liver (and *not directly* by the blood). Jaundice is produced.

10. The nerves of the submaxillary gland are the chorda tympani and sympathetic. Stimulation of the chorda tympani causes an abundant secretion of ordinary saliva, and vasodilatation. Stimulation of the cervical sympathetic causes a secretion of thick viscid saliva, with vasoconstriction.

Poralytic secretion: "If the chorda tympani nerve be cut on one side the submaxillary gland enters into a condition of what we might term 'overflow activity.' If a cannula be placed in Wharton's duct a constant slight dribbling of saliva occurs (about one drop in twenty minutes). This is known as 'paralytic secretion.' Sections of the gland present the typical appearances of a resting gland.

This condition is attended by a gradual atrophy of the gland, which may lose half its weight in a few weeks. Section of the sympathetic does not give rise to any analogous phenomenon, nor does it stop the paralytic secretion caused by section of the chorda."—(Starling's *Human Physiology.*)

CHEMISTRY.

1. (*a*) *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing these changes. (*b*) *Chemical compound* is a substance made up of two or more elements, chemically united, in definite proportions. (*c*) *Chemical affinity* is that force which attracts atoms together (to form molecules). (*d*) *Chemical reagents* are substances employed to produce chemical reactions.

2. An abnormal quantity of chlorine in drinking water generally indicates the presence of organic matter (sewage). *Test:* A solution of silver nitrate gives a precipitate in the presence of chlorides.

3. *Halogens* are: Fluorine, chlorine, bromine, and iodine. Fluorine is a gas, chlorine is a gas, bromine is a liquid, and iodine is a solid. They are all univalent, all are very irritant, all form hydracids and haloid salts, all have bleaching and disinfecting properties.

4. *Mercurous chloride*, calomel, Hg_2Cl_2, composed of two atoms of mercury and two atoms of chlorine to each molecule of the compound, insoluble in water, is a heavy white amorphous powder, without odor or taste, and if exposed to light becomes partially decomposed into mercury and corrosive sublimate.

Mercuric chloride, corrosive sublimate, $HgCl_2$, composed of one atom of mercury and two atoms of chlorine to each molecule of the compound, soluble in sixteen parts of cold water, is a white crystalline substance, with an acrid styptic taste.

5. A *normal solution* is one that contains to the liter the number of grams of the substance indicated by its atomic weight; a *decinormal solution* contains one-tenth of this number. Thus a liter of *normal* solution of sodium chloride contains $23 + 35.5 = 58.5$ grams of sodium chloride; a liter of *decinormal solution* contains 5.85 grams of sodium chloride.

6. $FeSO_4 + K_2CO_3 = FeCO_3 + K_2SO_4$.
$NH_4Cl + KNO_3 = KCl + N_2O + 2H_2O$.
$PCl_3 + 3H_2O = H_3PO_3 + 3HCl$.
$Zn + 2HCl = ZnCl_2 + H_2$.
$NH_3 + HCl = NH_4Cl$.

7. (*a*) The specific gravity of normal urine is about 1015 to 1025. (*b*) Specific gravity is *increased* in fevers and in diabetes mellitus; and decreased generally in Bright's disease and conditions of polyuria. (*c*) During the formation of a phosphatic calculus the reaction of the urine is alkaline.

8. (*a*) *Protcids* assume a purple-red color when warmed to 158° F. with Millon's reagent.

(*b*) *Phenol* assumes a lilac color when treated with solution of $FeSO_4$.

(*c*) *Lactic acid*, when added to Uffelmann's reagent, causes the latter to change from blue to yellow.

(*d*) *Amylum*, with dilute solution of iodine in potassium iodide, becomes blue.

(*e*) *Creosote*, with ferric chloride solution, gives a violet color, changing to green and brown.

9. Silver nitrate. *Composition:* $AgNO_3$; one atom of silver, one atom of nitrogen, and three atoms of oxygen to each molecule of silver nitrate. *Properties:* It is a crystalline solid, soluble in water, in the presence of organic matter it turns black in the sunlight, it is styptic, hemostatic, antiseptic, and irritant. *Names:* Argenti nitras, argentic nitrate, silver nitrate, lunar caustic, lapis infernalis.

10. (*a*) *Test for nitric acid:* Boil in a test tube some hydrochloric acid containing enough indigo-carmine to color it blue; add the suspected fluid, boil again; in the presence of nitric acid the color is discharged. *Antidote for nitric acid:* Solution of magnesia or strong solution of soap. (*b*) *Amalgams* are substances composed of two or more metals, one of which is mercury. (*c*) *Indicators* are substances which give different colors with certain classes of acid or alkaline substances. (*d*) *Ptomaines* are basic nitrogenous compounds produced from proteid material by the bacteria which cause putrefaction. They are produced from dead tissues. *Leucomoines* are produced in living vertebrate organisms. (*e*) Arterial and venous blood (see above, Physiology, 5).

MATERIA MEDICA.

1. *Alkaloids* are organic, basic, nitrogenous substances, existing in plants, of alkaline reaction, and capable of uniting with acids to form salts in the same way that ammonia does. *An infusion* is a liquid preparation made by treating vegetable substances with hot or cold water. A *decoction* is a liquid preparation made by boiling vegetable substances with water. *Fixed oils* are compounds containing the radical glyceryl with anhydrides of various fatty acids, and are capable of saponification. *Volatile or essential oils* are chiefly hydrocarbons, and are odorous principles found in plants or obtained therefrom, or even from the animal kingdom. They have not the chemical properties of fixed oils.

2. *Galactagogues:* Physostigma (tincture, ♏xv); Pilocarpus (fluid extract, ♏xxx).

Sialagogues: Pilocarpus (fluid extract, ♏xxx); Physostigma (tincture, ♏xv).

Emetics: Apomorphine (hydrochloride, gr. 1/10); Ipecac (wine of, ♏xx).

Antiseptics: Mercuric chloride, 1:1000; Formaldehyde, 1:100.

Anthelmintics: Aspidium (oleoresin, gr. xxx); Santonin, gr. j.

Diuretics: Potassium acetate, gr. xxx; Caffeine (citrated, gr. ij).

Antipyretics: Aconite (tincture, ♏x); Quinine (sulphate, gr. v).

3. Reduced iron, gr. j; ferrous carbonate, gr. iv; Basham's mixture, ʒiv; syrup of ferrous iodide, ♏xv; tincture of ferric chloride, ♏viij; iron and ammonium citrate, gr. iv.

4. Cinchona, gr. xv; fluid extract of cinchona, ♏xv; tincture of cinchona, ʒj; cinchona rubra, gr. xv; compound tincture of cinchona, ʒj; quinine, gr. iv; quinine sulphate, gr. iv; quinine bisulphate, gr. iv; quinine hydrobromide, gr. iv; quinine hydrochloride, gr. iv; quinine salicylate, gr. iv; cinchonine sulphate, gr. iv; cinchonidine sulphate, gr. iv.
